PRINCIPLES AND PRACTICE OF

Obstetrics and Gynecology
for Postgraduates

Federation of Obstetric and Gynaecological Societies of India
Disclaimer

The statements and opinions contained in the chapters of the book on Principles and Practice of Obstetrics and Gynecology for Postgraduates are solely those of the individual authors and contributors, and do not necessarily reflect the opinions or recommendations of the FOGSI.

Because of rapid advances in medical science, the editors recommended that independent verification of diagnosis or drug doses should be undertaken and references should always be made to the approved prescribing information for any product or procedure prior to its use.

Articles which have been published, become the property of FOGSI and should not be published or reproduced in full or in part without the permission of the editors. No part of this publication may be reproduced, stored in a retrieval system or transmitted in any form or by any means, electronic mechanical, photographing, recording, or otherwise without the prior written permission of the editors of the book.

As far as possible we have tried to incorporate the Vancouver system of references. However, since we are in transitional phase in some articles, we could not incorporate the same.

Dedicated to

Our teachers
for teaching us the Art and Science of Obstetrics and Gynecology and
for their major contribution in making us what we are today

Our patients
for their unstained faith in us, which has helped us to develop
our vast clinical experience and self-confidence

Our students
who continue to stimulate us to be researchers, teachers as well as students

Our families
for their support and for tolerating our repeated stints at various works and
for sharing their personal family time and of course
for supporting us and for always encouraging us

Federation of Obstetric and Gynaecological Societies of India (FOGSI)
for giving us an opportunity to express ourself and to serve Science and Humanity

The popularity of *Principles and Practice of Obstetrics and Gynecology for Postgraduates* has made us come out with the fourth edition.

In the rapidly advancing field of Obstetrics and Gynecology, new techniques, new treatments and modifications are happening rapidly.

A postgraduate student has to read many references, journals, Internet updates to keep abreast with all the rapid changes. This comprehensive multicontributor book, compiled by the members and the examiners of our own Federation of Obstetric and Gynaecological Societies of India (FOGSI), and updated by newly passed postgraduates and young lecturers, provides an in-depth, researched write-up on all the issues of obstetrics and gynecology.

The contributors have thoroughly researched and prepared the chapters along with clinical experiences and situations and cases peculiar to our country.

We are confident that this FOGSI textbook will be the main textbook for postgraduates in the field of obstetrics and gynecology. Not applicable only to students, we feel the textbook will be a referral guide for the busy practitioners also.

With due humility, we present the fourth updated edition of the *Principles and Practice of Obstetrics and Gynecology for Postgraduates*.

Narendra Malhotra

The field of Obstetrics, Gynecology and Family Welfare is a dynamic one. The truisms of yesterday are the questions of today and hopefully, the truths of tomorrow.

In this age of rapidly growing information and technology, there have been many noteworthy advances in the recent years which have had a major impact on the practice of Obstetrics and Gynecology changing social and cultural environment has brought with it different needs and expectations of the society from our specialty.

New technologies for diagnosis, treatment and prevention of disorders of the fetus have burgeoned in modern obstetrics, which has grown from the concept of merely assisting childbirth into a highly specialized field. The fetus as a patient has now become a reality for the obstetricians. Principles and Practice of Obstetrics and Gynecology for Postgraduates is the product of our attempt to advance these objectives.

This book has been written keeping in view the latest concept in the understanding of various obstetrics and gynecological conditions as well as their management, without omitting the basic principles and their applied pathophysiology. The text covers extensively topics relevant to the Indian context, like malaria, jaundice and other infections in pregnancy, which are rampant in the developing countries. Management of obstructed labor and the art instrumental delivery is still pertinent in our set-up. These are dealt with by the masters of these old and dying skills.

The reader is also apprised of the state-of-the-art technology in modern obstetrics and gynecology involving transvaginal ultrasonography, color Doppler, fetal surveillance and intrauterine interventions. The concept of auditing maternal morbidity and mortality has also been introduced to lay a firm foundation of clinical research and promote a logical approach instead of blindly following the traditional and irrational practices.

The authors have done a meticulous survey of the current literature and have amalgamated it with their rich experience to make the text a pleasurable reading. It has been our endeavor to see that the content of the book is both current and comprehensive; and this volume serves as a basic textbook for the postgraduates and as a handy reference for the practitioners.

In order to be a teacher, one must always be a student. Compiling and editing the book has been a personal learning experience.

Contents

SECTION 1: Prepregnancy Care

1. Preconception Care 3
   Prakash K Mehta (Chapter updated by Mohita Pengoria)
   • Early Trends 3 • Preconception Visit 3

2. From Safe Motherhood to Reproductive Child Health 7
   Alokendu Chatterjee, Joydeb Mukherjee, Partha Mukherjee, Nivedita Chattopadhyay
   (Chapter updated by Mohita Pengoria)
   • Definition and Causes of Maternal Mortality 7 • Safe Motherhood Initiative 8
   • Strategies of Safe Motherhood 8 • Health Care Interventions 9 • Reproductive and Child Health Program 11 • Road Ahead of Safe Motherhood 11

3. Principles of Antenatal, Intranatal and Postnatal Care at First and Second Referral Centers 13
   Maya Hazra, Nandita Maitra (Chapter updated by Mohita Pengoria)
   • Introduction: Magnitude of the Problem 13 • Trends in Development of Health Care Policies in India 14 • The National Rural Health Mission (2005–12) 15 • Community Mobilization Strategies 15
   • Rural Health Care System: The Structure and Current Scenario 15 • Maternal and Child Health Services at the Primary and Secondary Level 16 • Future Challenges 16

   Maninder Ahuja (Chapter updated by Mohita Pengoria)
   • Noncommunicable Diseases 18 • Maternal Mortality Epidemiological Evidence 19
   • Historical Trends in Recommendations for Weight Gain during Pregnancy 19
   • Factors affecting Fetal Growth 21 • Gestational Weight Gain 22 • India 24
   • Supplementation during Pregnancy 27 • Problems of Overweight 28
   • Reaching Women 32 • For Future Considerations 34

5. Maternal Exercises, Yoga and Dance Therapy 37
   Maninder Ahuja (Chapter updated by Mohita Pengoria)
   • Cochrane Review 37 • What are the Benefits of Exercise during Pregnancy? 38
   • Risks of Sedentary Lifestyle in Pregnancy 38 • When and How to Start an Exercise Program? 38 • Which Muscle Groups are Most Important to Exercise? 39
   • Protocol of Exercise 40 • Duration of Exercise 40 • Intensity of Exercise during Pregnancy 40 • Competitive Athletes and Pregnancy 42
   • The Actual Plan 43 • Instructions for Patient Education on Steps of Exercises: Body Weight Stretches 45 • Strength Training Exercises (Instruction for the Patients in Step of Exercises) 47 • Postpartum Exercise 49 • Exercise during Breastfeeding 49
   • Exercises for the Working Women 50

6. Genetic Counseling for Obstetricians 52
   Deepika Deka, Neerja Gupta, Madhulika Kabra (Chapter updated by Mohita Pengoria)
   • Genetic Counseling 52 • Prenatal Diagnostic Techniques 52 • Congenital Malformations and Genetic Disease Inheritance 53 • Neural Tube Defect 54 • Role of a Genetic Counselor 54
   • Indications of Prenatal Diagnosis and Genetic Counseling 55 • Genetic Counseling Case Management Procedure 55 • Genetic Counseling and Goals of Prenatal Diagnosis 55
   • Genetic Counseling and Prenatal Diagnosis for Genetic Disorders 58 • Genetic Counseling for Principal Indications 59 • Pre-test and Post-test Counseling for Biochemical Screening 61
   • Role of Obstetricians in Management of Patients with Genetic Disorder and Antenatal Detection of Malformation 61 • Special Problems in Genetic Counseling 61
   • Problems with Chromosomal Prenatal Diagnosis 62
SECTION 2: Medical Disorders in Pregnancy

7. Anemia in Pregnancy
   Manjari Matah, Partha Mukherjee, Arti Matah, Preeti Matah (Chapter updated by Meenal Jain)
   - Definition and Severity of Anemia in Pregnancy 67
   - Classification 67
   - Physiological Anemia of Pregnancy 68
   - Effects of Anemia on Pregnancy 68
   - Effects of Pregnancy on Anemia 68
   - Risk Periods for Maternal Mortality 68
   - Iron Deficiency Anemia 68
   - Dietary Sources of Iron 69
   - Prevalence 70
   - Causes 70
   - Clinical Features 70
   - Management 70
   - Diagnosis 70
   - Treatment 71
   - Iron Therapy 72
   - Management during Labor 75
   - Megaloblastic Anemia in Pregnancy 76
   - Folic Acid (Folate) Deficiency Anemia 76
   - Management 77
   - Vitamin B12 Deficiency Anemia 78
   - Management 78
   - Sickle Cell Trait (HbAS) 79
   - Sickle Cell Disease (HbSS) 79
   - Management 80
   - Treatment 80
   - Alpha Thalassemia Major 80
   - Alpha Thalassemia Minor 81
   - Beta Thalassemia Major 81
   - Beta Thalassemia Minor 81
   - Treatment 81
   - Hemolytic Anemia 81
   - Acquired Immune Hemolytic Anemia (Extravascular Hemolysis) 81
   - Microangiopathic Hemolytic Anemia (Intravascular Hemolysis) 83
   - Aplastic Anemia (Rare in Pregnancy) 84

8. Hematological Problems in Pregnancy
   Prakash K Mehta (Chapter updated by Meenal Jain)
   - Anemia Including Thalassemia and Sickle Cell Disease 86
   - Bleeding Disorders 87
   - Hypercoagulable States 89
   - Antiphospholipid Antibody Syndrome and Systemic Lupus Erythematosus 89
   - Leukemia/Leukemoid Reactions/Leukocytosis 90
   - Chronic Myeloproliferative Disorders 90

9. Hemoglobinopathies in Pregnancy
   Kavita N Singh (Chapter updated by Meenal Jain)
   - Sickle Cell Hemoglobinopathies 92
   - Management 94
   - Contraceptive Advice 95
   - Experimental Therapy 95
   - Thalassemia 96
   - Nestroft 98

10. Hypertension in Pregnancy
    Sunil Bansal (Chapter updated by Rekha Rani)
    - Normal Physiological Change in Blood Pressure during Pregnancy 99
    - Definition of Hypertension in Pregnancy 99
    - Classification of Hypertensive Disorders of Pregnancy 100
    - Pathogenesis of Preeclampsia 100
    - Management of Hypertension in Pregnancy 101
    - Antenatal Care 102
    - When to Treat Hypertension during Pregnancy 102
    - Antihypertensive Drugs to Avoid in Pregnancy 104
    - Antihypertensive Treatment Postpartum and during Breastfeeding 104
    - Risk of Recurrence of Hypertensive Disorders in a Subsequent Pregnancy 104
    - Long-term Cardiovascular Sequelae of Pregnancy-induced Hypertension 104
    - Managing Hypertension in Pregnancy: Key Points 105

11. Cardiac Disease in Pregnancy
    Tanya B Rohatgi, Kamal Buckshee (Chapter updated by Rekha Rani)
    - Cardiovascular Drugs 107
    - Management Options 108
    - Congenital Heart Disease 110
    - Atrial Septal Defect 110
    - Ventricular Septal Defect 110
    - Cyanotic Congenital Heart Disease 110
    - Eisenmenger's Syndrome 110
    - Pulmonary Hypertension 110
    - Marfan's Syndrome 110
    - Peripartum Cardiomyopathy 111
    - Myocardial Infarction 111
    - Mechanical Heart Valves 112
    - Acquired Heart Disease 112
    - Mitral Stenosis 112
    - Arrhythmias 112
    - Genetic Counseling 113
    - Heart Disease in Pregnancy: Key Points 113

    Tanya B Rohatgi, Kamal Buckshee, Sunil Bansal, Barun Sarkar (Chapter updated by Rekha Rani)
    - Management 116
    - Gestational Diabetes Mellitus 118

13. Liver Disease in Pregnancy
    Kaizad R Damania, Parikshit D Tank (Chapter updated by Rekha Rani)
    - Etiopathology 122
    - Viral Hepatitis 122
    - Acute Fatty Liver of Pregnancy 122
    - HELLP Syndrome 123
    - Clinical Presentation, Investigation and Differential Diagnosis 124
    - Management 125

14. Malaria in Pregnancy
    Hiralal Konar (Chapter updated by Rekha Rani)
    - Epidemiology of Malaria Complex 126
    - Pathology 127
    - Important Maternal and Fetal Complications 129
    - Effects of Pregnancy on Malaria 130
    - Management 130
    - Treatment 130
15. Thrombophilia in Pregnancy
SS Mehendale (Chapter updated by Poonam Yadav)
- Thrombophilia 133
- Mechanism of Clotting Disorders due to Inherited Defects 134
- Acquired Thrombophilia 135
- Clinical Presentation 136
- Treatment 137
- Future Perspectives 139

16. Pregnancy and Renal Disease
Alka Saraswat (Chapter updated by Poonam Yadav)
- Renal Disease Occuring during Pregnancy 141
  - Asymptomatic Bacteriuria 142
  - Acute Cystitis 142
- Acute Pyelonephritis 143
  - Acute Renal Failure 144
  - Chronic Renal Insufficiency 145
- Specific Types of Renal Disease 145
  - Pregnancy in Dialysis Patients 147

17. HIV Infection in Pregnancy
Alok Vashishtha (Chapter updated by Poonam Yadav)
- Reproductive Health Issues in HIV-infected Women 150
  - Methods of Conception in HIV-infected Patients 150
- Effects of Pregnancy on HIV Infection 151
  - Effects of HIV Infection on Pregnancy 151
- Impact of Antiretroviral Therapy on HIV Transmission 152
- Guidelines for Use of Antiretroviral Therapy in Pregnancy 154
  - Scenario 1 154
  - Scenario 2 154
  - Scenario 3 155
  - Scenario 4 156
- Perinatal HIV Transmission and Route of Delivery 157

18. Recurrent Spontaneous Abortions: Current Choices in Treatment
Mandakini Parihar, Meenakshi Bharath (Chapter updated by Poonam Yadav)
- Incidence 162
- Definition 163
- Etiology of Recurrent Spontaneous Abortions 163
  - Management of a Patient with Recurrent Spontaneous Abortions 164
  - Polycystic Ovary Syndrome Causing Recurrent Pregnancy Losses 165
- Genetic Abnormalities 165
  - Antiphospholipid Antibody (APLA) Syndrome 165

SECTION 3: Fetus as a Patient

19. Prenatal Diagnosis and Therapeutic Procedures
Vandana Chadda (Chapter updated by Poonam Yadav)
- Commonly Used Genetic Tests for Prenatal Diagnosis 173
- Common Diagnostic Procedures during Pregnancy
  - Noninvasive Screenings 174
- Invasive Techniques for Obtaining Fetal Sample 175
- Amniocentesis 175
- Chorionic Villous Sampling 176
- Fetal Umbilical Vein Sampling 177
- Embryo-fetoscopy 177

20. Fetal Infections
Hema Divakar, Anupama Rao (Chapter updated by Poonam Yadav)
- Presentation 179
- Diagnostic Techniques 179
- Details of Individual Infections 180

Pankaj Desai, Purvi Patel (Chapter updated by Ruchika Garg)
- Chances of Continuing the Pregnancy 188
- Genetic Factors and Recurrent Miscarriages 188
- Anatomical Causes and Recurrent Spontaneous Abortion 190
  - Uterine Fibroids 191
- Cervical Incompetence 191
- Infections and Recurrent Spontaneous Abortion 192
- Endocrine Dysfunction and Recurrent Spontaneous Abortion 192
  - Autoimmune Disease and Recurrent Spontaneous Abortion 193
  - Alloimmune Causes and Recurrent Spontaneous Abortion 194
- Unexplained Recurrent Pregnancy Loss 194
  - Psychological Aspects of Recurrent Spontaneous Abortion 194
  - Endometriosis and Recurrent Spontaneous Abortion 194
  - Toxic/Environmental Effects 195
  - Treatment 195

22. Intrauterine Growth Restriction: Diagnosis and Management
Uday Thanawala, Krutika Khopkar (Chapter updated by Ruchika Garg)
- Definition of Intrauterine Growth Restriction 199
  - Antepartum Recognition 200
  - Etiology 202
- Investigation 202
- Management 202

23. Controversies in the Management of Twin Pregnancies
Parikshit D Tank (Chapter updated by Ruchika Garg)
- Vanishing Twin 208
  - Preventing Preterm Delivery 208
  - Antenatal Care 209
- Problems Unique to Twin Pregnancies 210
  - Route of Delivery 210
  - Postnatal Issues 210
24. Preterm Premature Rupture of Membranes
Sarita Bhalerao, Trupti Nadkarni (Chapter updated by Ruchika Garg)
- Incidence
- Etiopathogenesis
- Risk Factors
- Management
- Consequences of PPROM
- Management of PPROM

Asha Oumachigui, Latha Chaturvedula (Chapter updated by Ruchika Garg)
- Etiology
- Epidemiology
- Identifying Women at Risk of Preterm Birth
- Evaluation of PTL
- Investigations
- Treatment of Preterm Labor
- Risk to the Neonate
- In Utero Transfer
- Intrapartum Management
- Prepregnancy Prevention of Preterm Birth

Duru Shah, Safala Shroff, Seema Jain (Chapter updated by Ruchika Garg)
- Antepartum Prophylaxis
- Postpartum Prophylaxis
- Monoclonal Versus Polyclonal
- Laboratory Techniques in Evaluating a Rhesus Alloimmunized Pregnancy
- Prenatal Investigations
- Investigations of the Fetus
- Clinician’s Approach to Rhesus Alloimmunization
- Management of the Erythroblastic Baby after Birth
- Rhesus Alloimmunization: The Future

27. Fetal Surveillance: Newer Developments
Jyotsna Gandhi (Chapter updated by Ruchika Garg)
- Nonstress Test
- Nonstress Test in Clinical Conditions
- Amniotic Fluid Volume/Index
- Umbilical Artery Doppler Velocimetry in Antepartum Fetal Surveillance
- Concept of a Combined Testing Plan

28. Fetal Echocardiography
Sonal Panchal (Chapter updated by Ruchika Garg)
- Risk Factors for Cardiac Anomalies
- Equipment Settings
- M-mode Study
- Evaluation of the Heart
- Study of Internal Cardiac Anatomy
- Four Chamber View
- Left Ventricular Outflow Tract
- Right Ventricular Outflow Tract
- Three Vessel View
- Short Axis View
- Arch/Longitudinal Views
- Fetal Circulation
- Classification of Cardiac Diseases
- Septal Defects
- Right Heart Anomalies
- Left Heart Anomalies
- Congotruncal Defects
- Single Ventricle Defects
- Other Cardiac Defects
- Arrhythmias

29. The Genetic Sonogram
Ashok Khurana (Chapter updated by Ruchika Garg)
- Definition and Background
- Sonographic Markers for Down’s Syndrome
- Trisomy 18 (Edwards Syndrome)
- Trisomy 13 (Patau Syndrome)
- Turner’s Syndrome (XO)
- Triploidy
- Genetic Sonography after First Trimester Screening

30. Fetal Therapy: Medical and Surgical
Deepika Deka (Chapter updated by Ruchika Garg)
- Medical Fetal Therapy
- Thyroid
- Congenital Adrenal Hyperplasia
- Nonimmune Hydrops
- Inborn Errors of Metabolism
- Alloimmune Thrombocytopenia
- Fetal Infections
- Toxoplasmosis
- Fetal Arrhythmias
- Cardiac Malformations
- Rhesus Isoimmunization
- Fetal Surgical Therapy
- Urinary Tract Obstructive Defects
- Lung Defects
- Pleural Effusion
- Multiple Pregnancies
- Congenital Diaphragmatic Hernia
- Fetal Tumors
- Sacrococcygeal Teratoma
- Recent Advances
- Fetal Gene Therapy

SECTION 4: Intrapartum Management

31. Place of Induction of Labor in Modern Obstetrics
Murari S Nanavati, Saloni Nanavati (Chapter updated by Anu Pathak)
- Incidence of Induction of Labor
- Indications for Induction of Labor
- Role of Cesarean Section
- Factors Influencing the Outcome of Induced Labor
- Methods of Cervical Priming
- Methods of Induction of Labor
32. Modern Management of Labor  
Shirish N Daftary (Chapter updated by Anu Pathak)  
- Admission Procedure 289  
- Partography 292  
- Active Management of Labor 292  
- Programmed Labor 294  
- Illustrative Cases 295  
- Dysfunctional Labor 297

33. Intrapartum Fetal Monitoring Controversies  
Rajyashri Sharma, Shaheen (Chapter updated by Anu Pathak)  
- Intermittent Auscultation 300  
- Electronic Fetal Monitoring 300  
- Internal or Direct Monitoring 302  
- Other Intrapartum Fetal Monitoring Techniques 302

34. Management of Obstructed Labor at a Referral Center  
Chandrawati, Priti Kumar (Chapter updated by Anu Pathak)  
- Etiology 308  
- Clinical Picture of the Obstructed Labor 310  
- Management 313  
- Complications 316

35. Instrumental Vaginal Delivery  
Atul Munshi, Dujal Munshi (Chapter updated by Anu Pathak)  
- Historical Aspect 318  
- Incidence 318  
- Indications 318  
- Prerequisites 319  
- Contraindications 319  
- Trial of Instrumental Delivery 320  
- Choice of Anesthesia 320  
- Classification of Forceps Deliveries 320  
- Application 321  
- Risks 323  
- Ventouse 323  
- Risks Related to Instrumental Delivery 324

36. Modern Management of Breech Presentation  
Vandana Walvekar, Pratima Anjaria (Chapter updated by Anu Pathak)  
- External Cephalic Version 330  
- Elective Cesarean 332  
- Trial of Breech (Vaginal Breech Delivery) 332  
- Dilemmas and Discussion 333

37. Changing Trends in Cesarean Section  
Neera Agarwal, Sumita Mehta, Shalini Rajaram (Chapter updated by Anu Pathak)  
- History of Cesarean Section 335  
- Incidence 335  
- Indication 336  
- Changing Trends in Operative Technique of Cesarean Section 337

38. Active Management of Third Stage of Labor  
MP Patil (Chapter updated by Anu Pathak)  
- Active Management 340  
- Oxytocic Drugs for Active Management of Third Stage of Labor 341

SECTION 5: Postpartum Conditions

39. Management of Postpartum Hemorrhage  
Maya Sood, Ritu P Khival, Anita Sabharwal (Chapter updated by Anu Pathak)  
- Definition 345  
- Etiopathology 346  
- Clinical Presentation 346  
- Diagnosis 346  
- Management 347

40. Puerperal Sepsis  
Madhuri A Patel, Usha B Saraiya (Chapter updated by Anu Pathak)  
- Historical Aspect 352  
- Predisposing Factors for the Development of Puerperal Sepsis 353  
- Septicemia and Septic Shock 354  
- Differential Diagnosis of Persistent Fever 355  
- Puerperal Sepsis 355

41. Breastfeeding Promotion  
Sonali Tank (Chapter updated by Mohita Pengoria)  
- Special Issues 361  
- How do We Promote Breastfeeding? 362

42. Postpartum Psychiatric Disorders  
KC Gurnani (Chapter updated by Mohita Pengoria)  
- Etiopathology 364  
- Clinical Presentations 365  
- Investigations and Diagnosis 366  
- Management 367  
- Prevention 369

43. Postpartum Exercises  
Meera Desai (Chapter updated by Mohita Pengoria)  
- Assessment 371  
- Diastasis Recti Abdominis 372  
- Pelvic Floor 372  
- Pelvic Floor Exercises 372  
- Abdominal Muscle Exercises 372  
- Pelvic Tilting 372  
- The Early Postnatal Class 374
Principles and Practice of Obstetrics and Gynecology for Postgraduates

44. Postpartum Collapse
Hiralal Konar, Saunitra Inamdar, Picklu Choudhury, Gayatri P Nagpure (Chapter updated by Meenal Jain)
- Management of Postpartum Collapse 379
- Amniotic Fluid Embolism 380
- Pulmonary Thromboembolism 381
- Acute Inversion of the Uterus 382
- Regional Anesthesia/Drug Toxicity or Self Poisoning (Suicide) 383
- Myocardial Infarction 383
- Hemorrhagic Shock 384
- Septic Shock 387
- Eclampsia 387
- Anaphylaxis 389
- Cardiomyopathy 389
- Aortic Dissection 389
- Deterioration of Cardiac Disease 389
- Stroke 389
- Inhaled Vomit Syndrome (Mendelson’s Syndrome) 389
- Cardiac Arrest 390
- Mortality What to Do 390

SECTION 6: Emergency in Pregnancy

45. Antepartum Hemorrhage
Sukanta Misra (Chapter updated by Meenal Jain, Mohita Pengoria)
- Incidence 395
- Causes 395
- Management 396
- Placenta Previa 397
- Abruptio Placentae 403
- Unclassified (Undetermined) Antepartum hemorrhage 407
- Vasa Previa 408

46. Tumors during Pregnancy: Management
DK Dutta (Chapter updated by Meenal Jain)
- Tumors Arising from Reproductive Organs 411
- Tumors Arising from Nonreproductive Organs (Intra-abdominal) 411
- Tumors Arising from Extra-abdominal Organs 411
- Ovarian Tumors during Pregnancy 411
- Effect of Fibroid on Pregnancy and Labors 412
- Cancer Cervix with Pregnancy 413
- Tumors Arising from Nonreproductive Organs (Intra-abdominal) 414

47. Surgical Emergencies during Pregnancy
Anupam Gupta, Sushma Gupta (Chapter updated by Meenal Jain)
- Maternal Physiologic Changes Relevant to Surgery 415
- Anesthesia during Pregnancy 416
- Specific Surgical Problems in Pregnancy 417
- Traumatic Injuries during Pregnancy 421

48. Critical Care in Obstetrics: An Overview
B Shakuntala Baliga (Chapter updated by Meenal Jain)
- Costs of Intensive Care 422
- Need for an Obstetric ICU 423
- Investigations to be Done in the Critically Ill Obstetric Patient 423
- Factors affecting Outcome of Critical Illness 423
- Illness Severity Scoring Systems 423
- Multiple Organ System Failure 424
- Invasive Hemodynamic Monitoring in the Critically Ill Obstetric Patient 424
- Drug Therapy during Intensive Care in Pregnant Women 425
- Radiologic Studies in Pregnancy 425
- Fetal Concerns during Critical Care 426
- Postmortem Cesarean Delivery 426
- Hypertensive Disorders of Pregnancy 426
- Sepsis 426
- Obstetric Hemorrhage 426
- Acute Respiratory Distress Syndrome 427
- Device-Associated Nosocomial Infections in the ICU 427
- The Need for an ICU at the Subdistrict and District Hospitals 428

49. Emergency Obstetric Care for Reducing Maternal Mortality
Sadhana Desai, Prakash Bhatt, Mandakini Parihar (Chapter updated by Meenal Jain)
- Maternal Mortality: A Burning Issue Worldwide 430
- Indian Scenario 430
- Causes of Maternal Deaths 431
- Key Strategies to Save Life of Pregnant Women 431
- Why Focus on Emergency Obstetric Care? 431
- Public Health Concept 431
- Defining Emergency Obstetric Care 433
- Federation of Obstetric and Gynaecological Societies of India and EMOC 433

SECTION 7: Family Welfare and Contraception

50. History and Development of Contraception
Manju Puri, Anjali Taneja (Chapter updated by Meenal Jain, Mohita Pengoria)
- Natural Methods of Contraception 437
- Barrier Contraceptive Methods 438
- Intrauterine Contraceptive Devices 438
- Hormonal Contraceptives 439
- Emergency Contraception 440
- Male and Female Sterilization 440

51. Natural Methods of Family Planning: Barrier Contraception
D Pushpalatha (Chapter updated by Meenal Jain)
- Natural Family Planning Methods 443
- Barrier Methods 445
52. Steroidal and Nonsteroidal Contraception  
Krishnendu Gupta, Bijit Chowdhury, Alokendu Chatterjee (Chapter updated by Meenal Jain)
- Steroidal Contraception  447  
- Nonsteroidal Contraception  451  
- Future Contraceptives  457

53. Abortion Practices  
Nozer Sheriar (Chapter updated by Meenal Jain)
- Current Status of Abortions  460  
- Characteristics of Abortion Seeker  460  
- Legal Status of Induced Abortions in India  461  
- Technical Nuances of Medical Termination of Pregnancy  462  
- Abortion Related Complications  463  
- Training Interventions  463  
- Vision for the Future  463

54. Complications and Sequelae of Medical Termination of Pregnancy  
Alka Saraswat, Manju Mataliya (Chapter updated by Meenal Jain)
- Complications due to Surgical Methods  466  
- Complications due to Medical Methods of Termination  468  
- Sequelae of Medical Termination of Pregnancy  470  
- Complications Remote from Abortion Procedure  470

55. Permanent Methods of Sterilization  
Pratap Kumar, Sreelakshmi (Chapter updated by Meenal Jain)
- Female Sterilization  473  
- Surgical Approach  475  
- Complications  475  
- What is Essure?  476

56. Social Work in Modern Medicine  
Girija Wagh, Shirish Patwardhan (Chapter updated by Meenal Jain)
- What is Social Work?  478

57. Intrauterine Contraceptive Device  
Milind R Shah (Chapter updated by Meenal Jain)
- History and Development  481  
- Types of Intrauterine Contraceptive Devices  482  
- Intrauterine System  484  
- Mechanism of Contraception  484  
- Effectiveness of Contraception  485  
- Timing of Insertion  485  
- Removal  487  
- Indications  487  
- Advantages  487  
- Disadvantages and Side Effects  488  
- Contraindications  488  
- Complications  489

58. Emergency Contraception  
Nayna A Dastur, Ameya C Purandare (Chapter updated by Meenal Jain)
- Definition  492  
- Indications  492  
- Epidemiosocial Aspects  492  
- Mode of Action  493  
- Contraindications  495  
- Drug Interactions Relevant to Emergency Contraceptive Use  496  
- Practical Management Following a Request for Emergency Contraception  496  
- After Care and Follow-up  496  
- Role of Various Organizations in Emergency Contraception  496

59. Medical Termination of Pregnancy Act: Interpretation and Implications  
Jaydeep Tank (Chapter update by Meenal Jain)
- Problem of Unsafe Abortion  499  
- Background  499  
- The Medical Termination of Pregnancy Act  500

60. Vasectomy and Male Partner Involvement in Family Planning and Welfare  
KM Nadkarni, Arun Tewari (Chapter updated by Meenal Jain)
- Indications  503  
- Technique of Vasectomy  504  
- Recent Developments  506

SECTION 8: General Gynecology

61. Approach to Abnormal Uterine Bleeding  
Jaideep Malhotra, Narendra Malhotra, Joshep Kurian, Neharika Malhotra (Chapter updated by Rekha Rani)
- Menstrual Physiology  511  
- Evaluation  513  
- Steps for Evaluation  513  
- Treatment  516  
- Treatment Options  516  
- Approach to a Case of DUB  518

62. Fibroids: Epidemiology, Etiopathophysiology and Diagnosis  
Joydeb Mukherjee, Gourisankar Kamilya, Subrata Lall Seal (Chapter updated by Rekha Rani)
- Epidemiology  521  
- Pathology  522  
- Etiopathogenesis  522  
- Clinical Features  524  
- Investigations  525

72. Genitourinary Fistula Repair
    Manu Sobti (Chapter updated by Urvashi Verma)
    • Incidence and Etiology 601 • Management 601 • Plan for Treatment 602 • Prevention of Genitourinary Fistulas 603

73. Decision Making for the Choice of Hysterectomy
    Shirish S Sheth, Kurush P Pagdiwalla (Chapter updated by Urvashi Verma)
    • Indications or Associated Conditions 610 • Examination Under Anesthesia 614 • Important Points to Remember When Choosing the Route for Hysterectomy 617

SECTION 9: Endocrinology

74. Female Endocrinology and its Clinical Relevance
    CB Nagori (Chapter updated by Urvashi Verma)
    • Two-cell System 621 • Ovary 623 • Puberty 625 • Physiology of Puberty 625 • Period of Infancy and Childhood 625 • Prepubertal Period 625 • Puberty 626 • Precocious Puberty 627 • Endocrinology of Ovulation 628

75. Disorders of Menstruation in Adolescent Age
    Parul J Kotdawala (Chapter updated by Urvashi Verma)
    • Menstruation in Adolescence 631 • Dysmenorrhea 632 • Amenorrhea 633 • Menorrhagia and Dysfunctional Uterine Bleeding 635

76. Hormone Therapy: Current Concepts
    Urvashi Prasad Jha, Ruchira Menka Jha, Swasti (Chapter updated by Neha Agarwal)
    • The Basket of Hormones 640 • Functional and Need-based Classification of Hormonal Therapy Use 641 • Tissue Selective Rationale of Hormone Use 642 • The Currently Enlarged Canvas of Hormone Therapy Actions 643 • Tailoring Therapy: Investigations Prior to Starting Hormone Therapy, Follow-up and Monitoring 650

77. Management of Hyperprolactinemia
    Sulochana Gunasheela (Chapter updated by Saroj Singh)
    • Conditions Associated with Increased Prolactin Secretion 654 • Management of Hyperprolactinemia 655 • Should Asymptomatic Hyperprolactinemia be Treated? 657 • Management during Pregnancy in Women with Prolactinoma 657

78. Polycystic Ovary Syndrome and Hirsutism
    Usha R Krishna, Pradnya Parulkar (Chapter updated by Neha Agarwal)
    • Pathophysiology 659 • Hyperandrogenism and Hirsutism 662 • Clinical Features 662 • Diagnosis of PCOS 663 • Differential Diagnosis 664 • Management 665 • Treatment of PCOS in Adolescent Girls 665 • Treatment of Menstrual Disturbances 666 • Hirsutism 666 • Treatment of Infertility 667 • Surgical Treatment 668 • The Pregnancy Outcome for Women with PCOS 669 • Long-term Health Implications in Women with PCOS 669

79. Luteal Phase Inadequacy
    Asha R Rao, Roopa J Pai (Chapter updated by Neha Agarwal)
    • Incidence and Etiopathology 671 • Ovulatory Events and Luteal Phase 671 • Pathophysiological Mechanisms of Luteal Phase Defect 672 • Luteal Phase Defect and Clomiphene Citrate 672 • Luteal Phase Defect in Controlled Ovarian Hyperstimulation 672 • Diagnosis of Luteal Phase Defect 672 • Treatment of Luteal Phase Defect 674

80. Hyperandrogenism
    Abha Majumdar, Tejshree Singh (Chapter updated by Saroj Singh)
    • Androgen Excess in Reproductive Life 678 • Androgens Production in Females 678 • Various Androgens Present in Females 679 • Estimation of Androgens 679 • Androgen Excess Manifest in Two Ways 679 • Effect of Androgen Excess on Ovulation/Reproductive Performance 680 • Disorders Leading to Androgen Excess in Reproductive Age Group Female 680 • Polycystic Ovarian Syndrome 680 • HAIR-AN Syndrome 681 • Congenital Adrenal Hyperplasia 681 • Cushing’s Syndrome 682 • Virilizing Ovarian Tumors 682 • Androgen-secreting Adrenal Tumor 683 • Hyperprolactinemia 683 • Acromegaly 684 • Iatrogenic Virilization 684
81. Thyroid and Adrenal Disorders in Gynecology
Snehamay Chaudhuri, Hiralal Konar (Chapter updated by Neha Agarwal)
- Disorders of Thyroid Function 685
- Thyroid Disorders and Infertility 686
- Thyroid Disorders and Menstrual Irregularities 687
- Thyroid Disorders in Relation to Gynecological Surgery 688
- Disorders of Adrenal Function 689

82. Clinical Approach to Primary Amenorrhea
Ashwini Bhalerao Gandhi, Vandana G Shetty (Chapter updated by Neha Agarwal)
- Basic Principles of Menstrual Function 692
- Pathological Amenorrhea 692
- Etiology of Primary Amenorrhea 692
- Management 698

83. Precocious Puberty: Clinical Dilemmas in Practice
Ashwini Bhalerao Gandhi, E Sarulatha (Chapter updated by Neha Agarwal)
- Puberty 700
- Factors Affecting the Onset of Puberty 700
- Precocious Puberty 701
- Recent Advances and Controversies 703

SECTION 10: Infertility

84. Basic Management of Infertility
Manish Banker, Pravin M Patel (Chapter updated by Neha Agarwal)
- Incidence 707
- Initial Infertility Evaluation 708
- Primary Evaluation 708
- Secondary Evaluation 715
- Basic Treatment of Infertility 715
- Assisted Reproductive Technologies 717

Prepregnancy Care
INTRODUCTION
The health care offered before conception in order to optimize the outcome of a given pregnancy constitutes the preconception care. It is the preventive care for women of reproductive age and their partners, including assessment by history and physical examination, counseling, education and intervention. Achieving good health before conception helps women to have healthier pregnancies with fewer complications. The continuity of care and the close physician-patient relationship in primary care offers an opportunity for the physician to assess risk factors and to intervene and modify behaviors that increase pregnancy risk. Education of males is also important since they often influence health risks and behaviors in the female. Preconception care must begin at least 3 months before planning a pregnancy.

EARLY TRENDS
Until 1941, the placental barrier was believed to protect the developing fetus from adverse exposure to environmental hazards. Studies of birth defects caused by rubella infection during pregnancy disproved this theory. Further progress toward protecting neonatal outcomes has included education and close management of insulin dependent diabetic women before and during pregnancy. This was later extended to various high-risk factors existing before pregnancy. The concept was then offered even to normal women as a primary preventive measure because it was realized that a woman’s health prior to pregnancy is important for successful pregnancy outcome.

PRECONCEPTION VISIT
A preconception visit should include:
1. History including medical history, family’s medical background, questions about diet and social habits, such as whether she drinks or smokes, past pregnancies, birth control use, medication and immunizations.
2. General physical examination including height, weight, blood pressure, thyroid, dentition, heart, breasts and signs of asymptomatic underlying disease.
3. Pelvic examination:
   - Infection identification: (1) signs of condylomata or herpes (2) vaginal discharge evaluated for Candida, Trichomonas, and bacterial vaginosis, cervical discharge culture for gonococci and Chlamydia
   - Cervical anomalies
   - Pap smear
   - Bimanual examination to rule out uterine and adnexal abnormalities
   - Ultrasound assessment in case of any clinical suspicion.
4. Laboratory evaluation: Complete blood count (CBC), blood group, Rh type. Infection profile [venereal disease research laboratory (VDRL), rubella, human immunodeficiency virus (HIV) and hepatitis B surface antigen], blood sugar, urine analysis and in indicated cases hemoglobin electrophoresis and cytomegalovirus (CMV) antibody titers.
Counseling Implications

Medical Disorders

Diabetes mellitus, epilepsy and hypertension are amongst diseases where it is worthwhile to bring the disease under optimal control before getting pregnant. In diabetes to prevent early pregnancy loss and congenital malformations, maternal nutrition 90–120 days prior to conception is believed to be as critical, if not more, as the early pregnancy nutrition. Maternal nutrition during Second World War revealed the vital need for good preconception nutrition to ensure healthy newborns.

A balanced, nutritious diet is advisable before conception and throughout pregnancy. Studies of the Dutch famine during Second World War revealed the vital need for good preconception nutrition to ensure healthy newborns. Maternal nutrition 90–120 days prior to conception is believed to be as critical, if not more, as the early pregnancy nutrition.7

Age-related Factors

Pregnancy in an adolescent girl encompasses problems in education, medical and social risks. Pregnancy in elderly encompasses another set of problems. Older women are more likely to have health problems, which could adversely affect pregnancy. In addition, previous gynecologic conditions or abdominal surgery may affect the mother’s ease in carrying or delivering the baby. For couples in their 30s and 40s considering parenthood, a common concern is the risk of having a baby with a genetic defect. The risk of chromosomal anomalies increases from 1 in 1,300 at 24 years to 1 in 100 at 40 years. The patient needs to be counseled regarding the need for invasive diagnostic procedures when pregnancy establishes.

Nutrition and Weight Gain

A balanced, nutritious diet is advisable before conception and throughout pregnancy. Studies of the Dutch famine during Second World War revealed the vital need for good preconception nutrition to ensure healthy newborns. Maternal nutrition 90–120 days prior to conception is believed to be as critical, if not more, as the early pregnancy nutrition.7

Special attention is required regarding intake of calcium and vitamins, and must include a folate supplement. Folate has been shown to reduce the rate of neural tube defects arising in the first few weeks of pregnancy often before a woman realizes she is pregnant.8 Similarly, pantothenate may help in decreasing the incidence of cardiac anomalies.

Young women in the current times are depriving themselves of sound nutritional habits to meet social images of feminine beauty. Primary care attempts to address this problem through education and counseling. However, poor nutrition due to poverty may be the single greatest risk factor for many future mothers. The role of client advocacy clearly comes into focus when the connection between poverty and at risk pregnancy or neonatal outcomes is made.

A woman should attempt to reach her ideal body weight (IBW) before conceiving. Women who weigh less than 90% IBW have increased risk for preterm or low birth weight infants.

Women who weigh more than 120% IBW have increased risk for gestational diabetes or hypertension. Reducing obesity before pregnancy increases the chances of having a healthy pregnancy.9

Eating disorders may cause nutrient deficiencies that should be corrected before pregnancy. The woman must also be informed that vitamin excesses, especially fat-soluble vitamins, may be toxic and possibly teratogenic.

Lifestyle Behaviors

Counseling regarding a woman’s social habits, such as tobacco and alcohol use, is another crucial part of a preconception visit. Discontinuing behaviors, which can be harmful to the developing fetus, including quitting smoking at least 3 months prior to conception is important. Smoking has been shown to influence fertility, cause miscarriage, low birth weight, preterm delivery and is considered a risk factor for sudden infant death syndrome.

Birth defects and growth retardation are known risk factors with alcohol consumption. Drinking alcohol beverages can cause fetal alcohol syndrome, a pattern of birth defects that includes mental retardation, cardiovascular, skeletal and facial abnormalities.10 Lower birth weight has been associated with fathers who drank prior to conception and passive smoking is also harmful to the fetus. Hence, the father to be has to be involved in these lifestyle changes. Intake of caffeine containing beverages must also be reduced, as it may delay conception and increase risk of abortion.11 A discussion regarding illicit, prescription and over-the-counter drug use and understanding the harm is also important.8

Environmental Challenges

Studies of occupational hazards and their effects currently support a much larger environmental risk of birth defects. Hazard protection for the worker often fails to include the
fetus.9 An example of this is the noise protection devices for workers exposed to high levels of noise. Testing of children exposed in utero revealed a threefold increase in development of a high frequency hearing loss greater than 4,000 decibels. The protective device the pregnant woman wears over her ears does not provide any protection for her developing fetus.

Another deficit is the safe levels of chemicals. Heavy metals like lead, copper and mercury, carbon disulfide, acids, and anesthetic gases can affect the developing embryo. With over 50,000 chemicals in the market, including household chemicals and insecticides, there are less than 100 animal studies to determine the effect of chemicals on human development. An adult’s safe level of chemical exposure is believed to be five to ten times higher than fetal tolerances. Fetal vulnerability is due to a high rate of cell division and differentiation, a small relative size, a lack of enzymes to metabolize drugs, and a less efficient excretory system.12

Protection from radiation (X-rays and effect of electromagnetic radiation), including exposure to it by living near high tensions wires and by use of microwave ovens and video display terminals, needs to be discussed. Knowledge of the dangers of physical stresses and strains to pregnancy are also important. Modern amusement park rides can generate high negative G-forces, which cause shearing affects known to cause placental abruptions. The early pregnancy is largely protein embryonic cells. Proteins undergo great changes at increased temperature. Hence, tub bath and infrared heat exposure may be harmful.

Infections
Rubella infection can cause serious birth defects if contracted during pregnancy. If the patient is not immune to rubella due to a prior episode, she can be vaccinated before pregnancy, but pregnancy should be delayed for 3 months after vaccination.9 Toxoplasmosis can seriously affect the fetus. Serological testing to identify immunity is worthwhile in high prevalence areas. A pregnant woman can help to avoid contracting toxoplasmosis by not eating undercooked meat or handling cat litter before she becomes pregnant and during pregnancy. All women must be preferably screened for hepatitis B. Uninfected women, especially those at high risk (such as health care workers who handle blood), can get protection from this infectious disease by vaccination. Local infections must be identified and treated before pregnancy is planned. For example, treatment of condylomata acuminata by podophyllin is contraindicated during pregnancy and hence treatment has to be completed before pregnancy. It is particularly important to screen for and treat bacterial vaginosis since it is associated with an increased risk of premature rupture of membranes, preterm birth, and histologic choriomeningitis. Counseling of HIV-positive couples regarding pregnancy outcome, antiretroviral drugs, breastfeeding and long-term implications is extremely important.

Contraception Usage
Few couples are aware that birth control pills should be discontinued several months in advance of pregnancy to allow at least two regular menstrual cycles to occur before conception. Women who take oral contraceptive agents may gain excessive weight and have an increase in serum cholesterol. An intrauterine device should also be removed a few months prior to pregnancy. Limitations and failure rates of various contraceptive methods must be discussed with the couple.

Drug Usage
Medication use by adult population is extremely common.13 A review of data14 regarding 15,2531 women who delivered between 1996 and 2000 revealed that in 64% of women, a drug other than a vitamin or mineral supplement was dispensed in the 270 days period before delivery. This included category C drugs dispensed to 37.8% and category D drugs dispensed to 4.8% of women. Moreover, drugs which are absolutely contraindicated in women who are pregnant (category X) were given to 4.6% of study population. A planned pregnancy helps in averting problems due to drug usage.

Fertility Treatment
High rate of multifetal gestation in treatments incorporating exogenous gonadotropins and other associated complications and failouts must be discussed.

Genetic Screening
Most couples do not require specific genetic screening before pregnancy. Information about background rate of birth defects needs to be given. However, some couples are at increased risk for genetic problems like thalassemia or Tay Sach’s disease, because of a family history of inherited disease or because of their ethnicity or geographic background. Consanguinity, individuals with abnormal genetic test result and recurrent miscarriage also require genetic counseling. Prepregnancy counseling is quite important in educating couples and helping them make educated decisions about their risk for birth defects or genetic disorders.12

Advantages of Prenatal Care
• Identifying the optimal time to try to conceive.
• Explanation of appropriate testing and procedure options including risks, benefits and limitations.
• The importance of getting adequate folic acid, iron and other nutrients both while trying to conceive and in early pregnancy.
• The dangers of smoking, alcohol and drug use.
• A discussion of the patient’s medical problems and/or those of her partner and its management by team approach.
• Accurate family and genetic history and identification of risk factors may reduce the incidence of birth defects.
Prepregnancy Care

• Updating woman’s immunization status.
• A review of safe activities during pregnancy (e.g. moderate exercise, sex, travel) as well as unsafe ones (e.g. contact sports and first trimester travel).
• Individual participation in health care. The woman can maintain control over her life during the process of conception and pregnancy. Protective environment at work and short-term transfer from job-deemed harmful to pregnancy may be planned.
• Pregnancy planning allows women to optimize their reproductive future. The proportion of infants born with a health disadvantage is significantly lower if the pregnancy was intended than if it was mistimed or not wanted.
• Patient support—facilitation of informed decision-making is available. Assistance in coping with psychosocial issues, education and coordinated patient care is possible.
• Early and complete antenatal care becomes a reality because of the continuum of the care process.

Changing Dynamics of Responsibility

Realistically, although parents want a perfect baby, the physician cannot fulfill this goal every time. Preconception care shifts this responsibility back to the parents. Better reproductive outcomes may be achieved with increased education and intervention on many levels. Average first prenatal visit occurs 10 weeks after conception when most of fetal organogenesis has already been accomplished, greatly reducing chance for outcome intervention. Preconceptual counseling can help to increase the odds for a healthy pregnancy and healthy baby. Preconception planning and a risk screening profile at the initiation of care helps the physician to define the client base by risk level and also the ability to pay for medical care.

Current Status

Many studies\(^8,12\) have found that performance is poor in providing preconception counseling. Deficiencies are noted in providing a healthy woman with information on rubella immunization and family planning or counseling on sexually transmitted diseases and safer sex. This warrants correction. The four components necessary for the successful practice of preventive health care including preconception care, that is, attitude, organization, appropriate knowledge and management skills, needs to be emphasized during the training of the residents in the field of gynecology.

CONCLUSION

Preconception care consists of three main components: (1) risk assessment, (2) health promotion and (3) intervention. Preconception care and early pregnancy care are excellent opportunities to modify the medical, social and behavioral risks on pregnancy outcomes and should be an integral part of primary care practice. Because over 50% of all pregnancies are unplanned, it is imperative that all gynecologists think of themselves as preconception health providers. The benefits are not likely to be fully realized unless primary care physicians include preconception care as a routine intervention for all women of reproductive age in their practice. The need for such care is greater in hospitals that serve large numbers of poor women, since the women most likely to benefit from preconception care, are often those least likely to have access to it.

From Safe Motherhood to Reproductive Child Health

INTRODUCTION

Maternal mortality (MM) is a truly neglected tragedy. Ninety-nine percent of maternal deaths occur in the developing countries and among women in the most deprived sections of the population. MM remains one of the most daunting public health problems in India. In the global scenario, according to the World Health Organization (WHO) there are about 529,000 maternal deaths per year with a global ratio of 400 maternal deaths per 100,000 livebirths.1

Around 136,000 maternal deaths occur in India (WHO, 2004). National health survey (1998–1999) by International Institute for Population Sciences (IIPS) published from Mumbai in 2000, reported maternal mortality ratio (MMR) at 540, while the Register General Report in 1998 found MMR 470. As high as 80% of MM is preventable. The women in the developing countries have a lifetime risk of death following complications of pregnancy, about 250 times more than that of the developed countries. The lifetime risk of maternal death in the world on the whole is 1 in 74, which varies from country to country and region to region. In the least developed countries the chances are 1 in 17, in the developing countries the risk are 1 in 61 and in the developed countries the chances are 1 in 4,000. Again for every death, there are 10 more that are left with morbidities of various kinds that may have lifelong crippling effects which the women endure in silence (Fig. 1).2–4 It is very rightly stated that MM is only the tip of the iceberg of maternal morbidity and women’s suffering.

DEFINITION AND CAUSES OF MATERNAL MORTALITY

The MMR means the number of death of women while being pregnant or during delivery or within 42 days of termination of pregnancy, irrespective of duration and site of pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental causes, per 100,000 livebirth. Although this statistics is often called the MM rate, it is not really a rate because the numerator (maternal death) is not a part of the denominator (livebirth). The causes of maternal death are multiple; they are divided into direct and indirect causes (Tables 1 and 2). Other causes contributing to maternal death are listed in Table 3.

Direct obstetric causes (80%)5 are those resulting from obstetric complications of the pregnant state (pregnancy,
SECTION

Prepregnancy Care

Table 1: Direct causes of maternal mortality
- Sepsis including unsafe abortion
- Obstetric hemorrhage
- Eclampsia
- Accident of labor
- Others

*Other direct causes include ectopic pregnancy, anesthesia related causes, embolism, etc.

Table 2: Indirect causes of maternal mortality
- Anemia
- Associated diseases
  - Cardiac
  - Renal
  - Hepatic
  - Metabolic
  - Infectious [including human immunodeficiency virus (HIV)]
- Malignancies
- Accident

Table 3: Contributory causes of maternal mortality
- Poor quality of health services including lack of proper infrastructure
- Inadequate obstetric care and essential supplies
- Poor maternal mortality audit
- Illiteracy, early marriage, poverty and malnutrition
- Unregulated fertility
- Ignorance—causes delay in making decisions during pregnancy
- Multiple demands on woman’s own time

labor and puerperium), from interventions, omissions, incorrect treatment, or from a chain of events resulting from any of the above (Table 1).

Indirect obstetric deaths (Table 2) are those resulting from a previously existing disease or a disease that developed during pregnancy and which was not due to direct obstetric causes, but which was aggravated by physiological effects of pregnancy. Investigators have found that 63–80% of direct maternal deaths and 88–98% of all maternal deaths could probably have been avoided with proper handling. Indian and global scenarios of maternal deaths are shown in Figures 2 and 3, respectively.

SAFE MOTHERHOOD INITIATIVE

It is global effort to reduce MM and morbidity and to reduce maternal deaths by at least half by 2010; safe motherhood initiative (SMI) was conceived in 1987 at Nairobi. It has also aimed to enhance the quality and safety of girls’ and women’s lives through adoption of a combination of health and nonhealth strategies. Partners of SMI are governments, different nongovernment organizations (NGOs), World Bank, United Nations International Children’s Emergency Fund (UNICEF), United Nations Fund for Population Activities (UNFPA), WHO, International Planned Parenthood Federation (IPPF), professional bodies and women’s group. As a matter of fact anybody and everybody can be a partner of this initiative. It lays emphasis on the need for better and more widely available maternal health services, the extension of family planning, education and services and effective measures aimed at improving the status of women. It may take many forms: increasing awareness of the magnitude of the problem and the need for action; strengthening maternal health services; training of health workers and others; facilitating educational and economic opportunities for women and research particularly operational research.

STRATEGIES OF SAFE MOTHERHOOD

If we compare the maternal health scenario between the developed and the developing countries (Tables 4 and 5), it becomes evident at MMR in developed countries is very low compared to developing countries. The reasons for massive reduction of MM in developed countries and very high in developing countries has been described below.

- Keeping the above information in mind, a strategy (Fig. 4) was taken in India in 1992, called child survival and safe motherhood (CSSM).
The tip of the pyramid shows health care programs of women for immediate results. Medium- and long-term goals are also defined.

HEALTH CARE INTERVENTIONS

The medical profession is responsible for delivering the obstetric health to all pregnant women. Obstetric health care means three “Es”.
1. Essential obstetric care for all.
2. Early detection of complications.
3. Emergency obstetric care (EOC).

Protocol for Essential Obstetric Care (Fig. 5)

It includes focused antenatal care with booking between 12 weeks and 16 weeks with at least five visits. Routine blood pressure and weight are recorded, along with obstetrical examination. Mandatory investigations like hemoglobin (Hb) percent, blood grouping and Rhesus (Rh) typing, urine sugar and protein are to be done. Two hours are postprandial blood sugar may be performed. Each woman is prescribed iron, folic acid and deworming agent after 16th weeks. Immunization against tetanus and proper care at birth must be taken. “5 clean” must be followed during birth care, clean hand, clean surface, clean razor blade, clean cord tie and clean cord stump. These services can be provided by auxiliary nurse midwife (ANM) or medical officer (MO) at health center and their local doctor or by trained birth attendant, preferably at the women’s locality. All health care providers must know when to refer the women to the nearest referral unit where EOC is available—this is the most important issue in the management of any obstetric complications, anywhere.

Early Detection of Complications

It is wise to remember that every pregnant woman is at risk of developing complications any time during pregnancy, labor and puerperium, and most complications cannot be predicted, also many complications cannot be prevented. Quality antenatal care can detect some complications early. It is always the first contact health providers who will detect the complications. In rural area, they are trained attendants/nurse midwives, family members and local practitioner. This group must be updated with the knowledge of signs of complications, e.g. bleeding anytime during pregnancy, convulsion, high fever, persistent headache and/or blurring of vision, excessive swelling of the body, less amount of daily urine output, prolonged labor pain and excessive bleeding after delivery, etc. and such cases should be referred to the nearest first referral unit (FRU).

Emergency Obstetric Care

The focus of safe motherhood programs in most developing countries has been on delivery of maternal services. The goal of reducing MM cannot be achieved, if prompt adequate care
is not available for obstetric complications. The challenge now is to shift the focus on EOC in addition to ongoing health care program. EOC includes specific interventions to manage specific emergency complications, which can be fatal within hours. It is agreed that 15% of all pregnant women will develop serious complications. Estimated average intervals from onset of complications to death are given in Table 6.

- No women should ideally deliver in a place which is more than 2 hours away from a referral unit. Apart from hemor rhage, there is usually enough time for a woman to be saved, supposing four frequent causes of delay are limited:
  - Delay in recognizing the problem
  - Delay in seeking care
  - Delay in reaching care
  - Delay in receiving care.

Emergency obstetric care will be of three types:
1. Obstetric first aid
2. Basic EOC
3. Comprehensive EOC.

Functions to define obstetric first aid:
- Oral misoprostol
- Parenteral oxytocics
- Parenteral antibiotics
- Parenteral anticonvulsants.

Functions to define basic emergency obstetric care (include in addition to obstetric first aid):
- Manual removal of placenta
- Forceps or vacuum extraction
- Evacuation of uterus in incomplete abortion
- Intravenous (IV) fluid administration. This can be done in community health centers.

**Comprehensive Emergency Obstetric Care**

It includes, in addition to the above, facilities for surgery, anesthesia and blood transfusion. The first referral hospital forms vital link between rural community and the centralized district hospital. MM can be reduced more by treating the complicated cases earlier and nearer home at first referral hospital either by specialists or by the physicians with 3–5 years experience who possess basic skills in obstetrics and surgery.

**First referral hospital or first referral unit:** It may be an upgraded health center, community health center or may be a district hospital. Staffs here are trained to perform essential obstetric functions. These are follows:
- **Surgical function:** Cesarean section, laparotomy for rupture uterus and tubal pregnancy, dilatation and evacuation, amniotomy, oxytocin infusion for augmentation of labor, repair of vaginal or cervical tears.
- **Anesthetic functions:** General/regional
- **Medical functions:** Treatment of shock, sepsis, hypertension, eclampsia and anemia.
- **Blood transfusion**
- **Manual or assessment functions:** Manual removal of placenta, vacuum extraction, forceps, parthography.
- **Family planning:** Tubectomy, vasectomy, intrauterine device (IUD) insertion, norplant insertion, etc.
- **Management of complicated pregnancy/labor referred from other levels.**
- **Neonatal care:** Resuscitation, thermal control and feeding.

Doctors, policy makers and health planners need to recognize that the objective of SMI to reduce MMR cannot be achieved by the existing services alone the provision of EOC at all level will be essential to bring about a sizeable decline in MM.
REPRODUCTIVE AND CHILD HEALTH PROGRAM

Phase I

The concept of reproductive health (RH), first introduced by Prof Fathalla, received a global acknowledgment during the International Conference on Population and Development (ICPD) (Cairo, 1994). ICPD defines RH as “a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity in all matters relating to the reproductive system, its function and process with a lifetime perspective”. The main issues of reproductive and child health (RCH) program are the integration of all interventions relating to improve facilities of obstetric care, medical termination of pregnancy (MTP), IUD insertion in the public health centers (PHCs), specialist centers for sexually transmitted disease (STD) and reproductive tract infection (RTI) in all district hospitals and number of subdivisional hospitals, setting up of FRU at subdistrict level providing comprehensive EOC, integration of all interventions of fertility regulation, maternal and child health with RH for both men and women. RCH phase I program had incorporated safe motherhood components along with child survivor components including STD and RTI. The RCH program was launched on 15th October, 1997. The RCH program integrated all the services of CSSM and the major interventions like essential obstetric care, 24 hour delivery services at PHCs/community health centers (CHCs), EOC, MTP, prevention of RTI and STD.

Phase II

This phase II began from 1st April 2005 with a focus to reduce maternal and child morbidity and mortality along with an emphasis on rural health center. The major strategies under the RCH phase II are:

- Essential obstetric care
  - Institutional delivery
  - Skilled attendance at delivery
- Emergency obstetric operational FRU
  - Operationalizing PHCs and CHCs for 24 hours delivery services
- Strengthening of the referral system.

Recent initiatives have been taken to provide adequate training of the MBBS doctors in life-saving skills for EOC. This provision of adequate and EOC has been recognized as the most important intervention for saving lives of pregnant women with complications.

ROAD AHEAD OF SAFE MOTHERHOOD

Making Pregnancy Safer

Making pregnancy safer (MPS) is a health sector strategy launched by WHO (2000) for reducing maternal and perinatal mortality and morbidity.

The MPS strategy builds upon the lessons of SMI, existing national efforts and the consensus reached at the ICPD (Cairo, 1994), world conference on women (Beijing, 1995) and the joint WHO/UNFPA/UNICEF/WORLD Bank Statement (1999).

The universally agreed goals in maternal health include:

- Eighty percent childbirths be assisted by skilled attendants by 2005.
- In areas with very high MMR, at least 40% of births be assisted by skilled attendants by 2005, 50% by 2010 and 60% by 2015.
- Reducing pregnancy related mortality by 75% by 2015.
- Reducing infant mortality rate (IMR) below 35 per 1,000 livebirths by 2015.

Three Making Pregnancy Safer Messages

1. Every pregnancy ought to be wanted.
2. All pregnant woman and their infants should have access to skilled care.
3. Every woman should be able to reach a functioning health facility in good time to obtain appropriate care when complications arise during pregnancy, delivery or the puerperium period.

Making pregnancy safer call for following essential services which could prevent up to 80% of maternal and newborn deaths.

- Family planning information and services
- Postabortion care
- Basic antenatal and postpartum care
- Skilled attendance during pregnancy, delivery and postpartum period
- Referral centers for complications.
Millennium Development Goals

This is described elsewhere.

The Partnership for Maternal, Newborn and Child Health

The partnership is a global health partnership launched in September 2005 and joins the maternal, newborn and child health (MNCH) communities into an alliance of some 130 members to ensure that all women, infants and children not only remain healthy, but also thrive. Ottawa, 21st June 2007—a meeting of Canadian and international health professionals was held to discuss why a half-million mothers are still dying each year. "Certainly, progress has been made in many areas," said Dr Dorothy Shaw, President of the International Federation of Obstetrics and Gynecology. "But it is a humbling experience that on the 20th anniversary of these goals, we still have a half-million women dying every year."

Geneva, 15th May 2007—The 60th World Health Assembly of the WHO gave prominence to the issue of MNCH.

Dar es Salaam, 17th April 2007—Prime Minister of Tanzania called on regional leaders to increase health spending to 15% of national budgets and to strive for achieving health millennium development goals (MDGs).

CONCLUSION

The challenge of reducing maternal morbidity and mortality is substantial and there are no simple solutions. The main priority should be for women to have the choice to deliver in any health center or hospital. Ensuring appropriate provision of EOC is an essential feature of all intrapartum care strategies, but timely access is crucial. Alternative approach to increase effective intrapartum care strategies is the availability of skilled birth attendants at home. During the last 20 years of International and National Advocacy for Safe Motherhood, an estimated 10 million women have died of maternal causes though 88–98% of maternal deaths are preventable. The International Federation of Gynecology and Obstetrics (FIGO) world report 2006 is dedicated to women of all ages and their children, who have lost their lives because their rights were not translated into meaningful action. FIGO, through collaboration with others, is committed to actions that will result in the respect of sexual and reproductive rights and access to health for women throughout the world.

INTRODUCTION: MAGNITUDE OF THE PROBLEM

Childbirth is a biological function and an integral part of the social environment, bringing joy to the mother and family. This can turn into a tragedy where a woman loses her child or suffers a catastrophe herself, while performing this social obligation.

According to the latest annual report 2007-09 of the Department of Health and Family Welfare (DoFW), Government of India (GOI), the national average of the maternal mortality rate (MMR), i.e. maternal deaths per lakh livebirths, in the country is 212. Each year in India, roughly 30 million women experience pregnancy and 27 million have a livebirth. With an estimated 136,000 deaths, India has the highest burden of maternal mortality in the world. Most of the maternal deaths are concentrated in the age-group of 20–24 years [National Family Health Survey 3 (NFHS-3)]. Forty seven percent of maternal deaths in rural India are attributed to anemia and hemorrhage. Abortions are the third leading single cause of maternal mortality being responsible for 12% of the deaths. According to Sample Registration System (SRS) 1998, sepsis accounts for 16%, obstructed labor for 10% and toxemia for 8% of the total maternal mortality.

Regional disparities in maternal and neonatal mortality are wide. It is also recognized that delays in accessing specialized maternal care happens at all levels. Only 42.5% of all births are attended by skilled health staff. The estimates of maternal mortality at State/Union Territories (UTs) levels not being very robust, MMR can only be used as a rough indicator of the maternal health situation in any given country. Hence, other indicators of maternal health status like antenatal checkup, institutional delivery and delivery by trained personnel, etc. are used for this purpose.

Nearly two-thirds of the maternal deaths occur in the Empowered Action Group (EAG) States including Uttar Pradesh, Uttaranchal, Madhya Pradesh, Chhattisgarh, Rajasthan, Jharkhand, Bihar, Orissa and Assam. The MMR was the lowest in Kerala (81), followed by Tamil Nadu (97), Maharashtra (104), Haryana (153), Gujarat (148), Punjab (172), West Bengal (145), Andhra Pradesh (134), Karnataka (178), Orissa (258), Bihar (261), Madhya Pradesh (269), Assam (390), Rajasthan (318) and Uttar Pradesh (359).

With 16% of the world’s population, India still accounts for over 20% of the world’s maternal deaths. Every 5 minutes a woman dies of pregnancy-related causes. It is estimated that for each woman who dies, 30 others develop chronic, debilitating conditions that seriously affect the quality of life.
TRENDS IN DEVELOPMENT OF HEALTH CARE POLICIES IN INDIA

The Ministry of Health and Family Welfare is the apex executive organization dealing with the issues of health and family welfare in the country. It also lays the National Health Policy in accordance with the policy decisions of the Cabinet. In 1986, World Health Organization (WHO) convened a Technical Working Group to define the essential obstetric care (EOC) necessary at first referral level for the reduction of maternal mortality and morbidity, and to describe the staff, training, supervision, facilities, equipment and supplies needed. This definition of EOC at first referral level has been of invaluable service to health planners of maternity services. However, it has not helped to reverse the polarization that has existed for 25 years between the development of hospital maternity services on the one hand and the training of traditional birth attendants (TBAs) on the other.

Two important milestones of the National Health Program of India to reduce maternal mortality were a policy shift from a vertical immunization program to a comprehensive Child Survival and Safe Motherhood (CSSM) initiative, and the strategic programmatic change from a high-risk approach to implementation of EOC, including the establishment of first referral units (FRUs). Health units which were either community health centers (CHCs) or subdistrict hospitals were identified to function as FRUs throughout the country. Second referral units consist of the district level hospitals and Medical College Hospitals.

Subsequently, India accepted the recommendations of the International Conference on Population and Development (ICPD) (1994) and in 1997 the Reproductive and Child Health (RCH) Programme was initiated, incorporating the components of the CSSM program and including the additional component of sexually transmitted diseases and reproductive tract infections.

RCH II: Strategic Choices to Reduce MMR

The RCH Programme, which was launched on October 15, 1997, draws its mandate from the Programme of Action of the ICPD, 1994. Under the RCH Programme, a comprehensive package of services for family planning (FP), maternal and child health and management of reproductive tract infections, including sexually transmitted diseases is being implemented. The key maternal health strategies under the RCH II phase which began on April 1, 2005, are:

- Essential obstetric care
- Skilled attendance at birth (domiciliary and health facilities)
- Operationalize emergency obstetric care at FRUs
- Strengthen referral systems
- Promote institutional deliveries
- Safe abortion services at primary health center (PHC) level.

The main priority of the RCH-II will be the operationalization of all CHCs and at least 50% of PHCs to provide 24-hour safe delivery and basic emergency obstetric care (BEmOC) by 2010. Emergency obstetric care (EmOC) is generally categorized as BEmOC and comprehensive EmOC (CEmOC) (Table 1). United Nations (UN) guidelines recommend a minimum of one comprehensive EmOC facility and four basic EmOC facilities per 500,000 population. Under the RCH phase II, two levels of institutions will be targeted:

1. PHCs and CHCs for BEmOC
2. FRUs for CEmOC.

**Anesthesia for EmOC Training for MBBS MOs**

One of the principal reasons for the failure of the RCH I Programme to operationalize the planned 1,748 FRUs was the lack of anesthetic services.

Department of Health and Family Welfare has developed a 14-week course in anesthesia for EmOC for MBBS Medical Officers (MOs). The first batch completed training at AIIMS last year. By 2010, 4,000 MOs will be trained to address the acute lack of anesthetic skills for EmOC at FRUs.

**Training MBBS MOs in Cesarean Section**

In view of the nonavailability of obstetricians at FRUs, the Federation of Obstetric and Gynecological Societies of India (FOGSI) has developed an EmOC course including cesarean section for MBBS MOs. This important step in capacity building in CEmOC and operationalization of FRUs will be implemented in a stepwise manner. A pilot phase will be evaluated before scaling up.

The National Population Policy (NPP) adopted by the GOI in 2000 reiterates the Government’s commitment to the safe motherhood program within the wider context of reproductive health. Among the National Socio-demographic Goals for 2010 specified by the policy, several goals pertain to safe motherhood, 80% of all deliveries should take place in institutions by 2010, 100% deliveries should be attended by trained personnel, and the maternal mortality ratio should be reduced to a level below 100 per 100,000 livebirths.

**THE NATIONAL RURAL HEALTH MISSION (2005–12)**

The National Rural Health Mission (NRHM) (2005–12) seeks to provide effective health care to rural population throughout the country with special focus on 18 states, which have weak public health indicators and/or weak infrastructure. Under this scheme, every village/large habitat will have a female Accredited Social Health Activist (ASHA)—chosen by and accountable to the panchayat—to act as the interface between the community and the public health system. ASHA would act as a bridge between the Auxiliary Nurse Midwife (ANM) and the village, and be accountable to the Panchayat. She will be an honorary volunteer, receiving performance-based compensation for promoting universal immunization, referral and escort services for RCH, construction of household toilets and other health care delivery programs. A key strategy of the Mission is operationalizing 3,222 existing CHCs (30–50 beds) as 24-hour FRUs, including posting of anesthetists.

**COMMUNITY MOBILIZATION STRATEGIES**

Learning from the lessons of RCH I, RCH II has evolved innovative strategies to stimulate demand for safe delivery and other RCH services.

**Janani Suraksha Yojana**

*Janani Suraksha Yojana* (JSY) is a modified version of the National Maternity Benefit Scheme. Its twin objectives are:
- To reduce maternal and infant mortality through promotion of institutional deliveries
- To protect the female fetus and child.

Pregnant women belonging to below poverty line (BPL) are eligible. The pregnant woman choosing institutional delivery receives financial assistance:
- Assistance (₹1,500) is provided for cesarean delivery.
- Transport assistance (₹150) is provided to a rural woman for traveling to a health center for delivery.
- Traditional Birth Attendants who mobilize women for antenatal care, institutional delivery and postnatal care are provided with financial assistance.

**Vande Mataram Scheme**

The Government has recently launched a scheme to involve private sector in safe motherhood/FP activities. Under this scheme, the gynecologist members of FOGSI volunteer are to provide free outpatient care services (antenatal and FP) to pregnant women on a fixed day each month. Doctors who are not members of FOGSI are also welcome. Each enrolled Vande Mataram physician is provided a kit, consisting of iron-folic acid (IFA) tablets, condoms, oral contraceptives (OCs) and intrauterine devices (IUDs) by the government for free distribution to patients. The scheme was launched on February 9, 2004.

**The Integrated Management of Neonatal and Childhood Illnesses Approach**

The objectives of Integrated Management of Neonatal and Childhood Illnesses (IMNCI) plus strategy in RCH II are to:
- Implement by 2010, a comprehensive newborn and child health package at the level of all subcenters (SCs) (through ANMs), PHCs (through MOs, nurse and Lady Health Volunteers (LHVs)) and FRUs (through MOs and nurses).
- Implement by 2010 a comprehensive newborn and child health package at the household level in 250 districts.

**Public-Private Partnerships**

Strong partnerships between the DoFW, GOI, state Government and the NGOs are being encouraged. DoFW will provide technical assistance, the state government will provide leadership to the project, and the private sector will be economically and formally engaged for service delivery to fill in gaps. There is a considerable capacity among private providers [nongovernmental organizations (NGOs), medical practitioners and other agencies] which is being explored and operationalized. Such partnerships are particularly likely to be viable in urban areas.

**RURAL HEALTH CARE SYSTEM: THE STRUCTURE AND CURRENT SCENARIO**

Flow chart 1 shows the rural health care delivery system in India.

**Subcenters**

The subcenter is the most peripheral and first contact point between the primary health care system and the community. Each SC is manned by one ANM and one Multipurpose Worker (Male) [MPW(M)]. One Lady Health Worker (LHV) is entrusted with the task of supervision of six SCs. SCs are assigned tasks relating to interpersonal communication in order to bring about behavioral change and provide services in relation to maternal and child health, family welfare, nutrition, immunization, diarrhea control and control of communicable diseases programs. The Department of Family Welfare is providing 100% central assistance to all the SCs in the country since April 2002. There are 144,988 SCs functioning in the country as on March, 2006.

**Primary Health Centers**

Primary Health Center is the first contact point between village community and the MO. The PHCs were envisaged to provide an integrated curative and preventive health care services.
care to the rural population with emphasis on preventive and promotive aspects of health care. A PHC is manned by a MO supported by 14 paramedical and other staffs. It acts as a referral unit for six SCs. It has 4–6 beds for patients. The activities of PHC involve curative, preventive, primitive and Family Welfare Services. There are 22,669 PHCs functioning as on March, 2006 in the country.

**Community Health Centers**

Community health centers are being established and maintained by the State Government under Minimum Needs Programme (MNP)/Basic Minimum Services (BMS) program. It is manned by four medical specialists, i.e. Surgeon, Physician, Gynecologist and Pediatrician, supported by 21 paramedical and other staffs. It has 30 indoor beds with one operation theater (OT), X-ray, labor room and laboratory facilities. It serves as a referral center for four PHCs, and also provides facilities for obstetric care and specialist consultations. As on March, 2006, there are 3,910 CHCs functioning in the country.

**MATERNAL AND CHILD HEALTH SERVICES AT THE PRIMARY AND SECONDARY LEVEL**

Figure 1 shows the antenatal, intranatal and postnatal services at the PHC and CHC level.

**FUTURE CHALLENGES**

Many systemic problems in the government, in General Health and Family Welfare Department in particular, affect the implementation of most health programs, CSSM or RCH being no exception. The goal is to achieve optimal health for all the people, which would allow them to lead socially and economically productive lives. Despite the commitment to the program, enormous health problems still need to be addressed. The major constraints facing the health sector are a lack of resources, large vacancy of posts and frequent transfer of staff, lack of an integrated multisectoral approach, insufficient information, education and communication (IEC) support, poor involvement of NGOs, poor disease
surveillance and response systems and a manually operated health management information system.

**REFERENCES**

INTRODUCTION

Ancient folklore and medical knowledge emphasize that the mother-child dyad (Fig. 1) is a vulnerable group from a health and nutritional point of view. Nutritionists have shown that these segments not only require more dietary intake but are also more susceptible to adverse health consequences following nutritional deprivation. Global studies have unequivocally demonstrated the association between undernutrition and increased risk of maternal, perinatal and infant mortality and morbidity. Clinical trials of food supplementation to undernourished groups suggest that reduction in morbidity and mortality rates and improvement in birthweight and growth in infancy could be achieved by food supplementation and proper nutrition.

But now it is not only deprivation but preconceptional obesity also which predisposes mother for various complications as well as various fetal complications and development of metabolic syndrome later on in life. So nutrition in mother has changed from scarcity to adiposity and would have to be studied from various angles.

NONCOMMUNICABLE DISEASES

Other new aspect which is developing in relationship to maternal nutrition and nutrition on the whole is the emergence of higher incidence of noncommunicable diseases (NCDs).

A recent analysis of mortality trends suggests that large increases in NCDs have occurred in developing countries, particularly those in rapid transition (e.g. Brazil, China and India). According to these estimates, at least 40% of all deaths in developing countries are attributable to NCDs (versus 75% in industrialized countries). Dietary deficits and excesses, and the lifestyle changes that accompany industrialization and urbanization with economic development make a significant contribution to this epidemic. Maternal deaths per minute, related to pregnancy are shown in Figure 2.

As is well recognized, making reproduction and childbirth safer, benefits not only women, but also newborns, children, families and ultimately the communities and nations!

Fig. 1: Mother-child dyad
MATERNAL MORTALITY

EPIEMIOLOGICAL EVIDENCE

World Health Organization Southeast Asian Region (SEAR) accounts for nearly one-fourth of the world’s population; most countries in the region have very young populations, with nearly 50% in the reproductive age group. Consequently, the number of pregnant women and the number of babies born annually are very large. An estimated 37 million childbirths take place annually. The region has about 180 million children under the age of five. Unfortunately, the region also accounts for more than 170,000 maternal deaths and over 3 million child deaths annually. These account for almost 33% of all maternal deaths worldwide. These statistics make the issue of maternal, newborn and child health a major priority for the region.

However, these deaths are not spread equally across the region, and there are vast intra-country and as well as intra-region variations (Fig. 3), especially in terms of inequity in access to skilled care at birth.

Equally, the proportion of newborn deaths is enormous—of the estimated 4 million neonatal deaths annually, 1.4 million newborns die in the first month after birth in countries of the SEAR (Table 1).

Relatively few reports exist on the relationship between maternal nutrition and preterm birth. Although some studies have reported an association between the two, it appears that maternal nutrition during pregnancy is not an important factor for prematurity. Poor maternal nutrition has however been shown to be one of the major causal determinants of intrauterine growth restriction (IUGR) in both developed and developing countries (Figs 4A and B). In developing countries, many women are short and underweight and the number of low birthweight (LBW) babies is particularly high (more than 30% in South Asia, 10–20% in other regions (Table 2).

Many efforts have been made in order to identify a potential “modifiable” factor for LBW. Maternal nutrition is modifiable in the short term; if it is one of the major environmental causes of IUGR in the developing world, a substantial fraction of LBW could possibly be prevented. In turn this might reduce the prevalence of mortality, morbidity, physical and mental development, factors associated with LBW.

HISTORICAL TRENDS IN RECOMMENDATIONS FOR WEIGHT GAIN DURING PREGNANCY

In the 16th, 17th and 18th centuries much emphasis was placed on the maternal diet since the mother was known to be the only source of nutrients for the fetus. In 19th century the idea that pregnant women should not overeat became a recurrent theme. Overeating was believed to be a cause of
large babies and as a consequence more difficult labors and so when maternal mortality was extremely high and cesarean deliveries were a desperate attempt, limitation of fetal size by restraining maternal food intake was an advice. This formed the basis of first published study of diet and pregnancy and this showed that restricting food intake throughout pregnancy reduced the birthweights of males by 400 g and of females by 500 g.

This formed the basis for the fact that maternal weight gain could be used as an indicator of maternal nutritional status and in turn influenced fetal growth. In 1920, Davis; Mcllroy and Roadway, 1937; Bingham, 1932, all advocated to control

weight gain and some advised even salt-free diets to control toxemia.

But it was in 1970 that a comprehensive report entitled “Maternal Nutrition During the Course of Pregnancy” was published (NRC 1970a) which reviewed problems, practices and research bearing on the relations between nutrition, and the course and outcome of pregnancy, and provided recommendations for weight gain and intake of nutrients.

After publication of this report a number of other studies showed that desirable weight gain during pregnancy varies as a function of prepregnancy weight for height and there was evidence to show that in order to achieve proper fetal weight women with adequate height and weight should gain more weight during pregnancy and overweight women should not gain much weight during pregnancy. So the importance of maternal nutrition with gestational weight gain centered the attention on outcome of birthweight, as in epidemiological studies birthweight is the outcome most frequently examined as its association with infant mortality and morbidity is widely recognized (Tables 3 and 4).

1990 report of the IOM, Nutrition During Pregnancy, was written at a time when concern was focused on insufficient gestational weight gain and concerns about LBW. In the intervening years, the larger context has shifted in light of increasing rates of obesity to create concern about too much weight gain, and prepregnancy overweight.
FACTORS AFFECTING FETAL GROWTH

- Nutrition has many components and energy in the form of carbohydrates is important. Glucose is a critical fetal nutrient, and if its supply is reduced growth restriction may result. Sokol et al. and Langer et al. have confirmed that a flat maternal response to glucose loading is associated with an increased risk for fetal growth restriction.

- In one study, it was proved that protein malnutrition before 26 weeks can cause IUGR.

- There is also an intergenerational effect: Women who were born of LBW mothers are more likely to have a LBW child (and even grandchild). This may be because of a metabolic adjustment to assure a fetal weight that is proportional to maternal size.

- Little work has been conducted to relate prepregnancy micronutrient intakes or status to LBW; however, suggests that acquiring a desirable weight and diet during the weeks before and around conception is highly recommended, especially in industrial populations where only subclinical micronutrient deficiencies exist. In developing countries, where a lifetime of very low intakes of micronutrients may exist, it is important to try to reverse these low intakes long...
before conception, but increasing intakes shortly before and during pregnancy may also help increase birthweight and survival chances of infants.

However, a recent study in the UK found that inadequate maternal micronutrient and fiber intakes early in pregnancy were more important in determining LBWs than low protein or energy intake. In this study, women had intakes of fiber and ten of the micronutrients (riboflavin, niacin, pyridoxine, thiamin, folic acid, iron, magnesium, phosphorus, calcium, and zinc) that were more than 20% below the reference requirement.

**GESTANATIONAL WEIGHT GAIN**

This is an important variable of interest that has been studied extensively but it needs further attention. Gestational weight gain has three components:

1. The products of conception, i.e. the fetus, the placenta, and the amniotic fluid
2. The fluids in the extra tissue gained by the mother to support the pregnancy

Roughly, 70% consists of the pregnancy components and 30% is thought to be attributed to maternal stores.

The largest component of gestational weight gain is water, followed by fat (the most variable of all of the components in the literature), and finally protein.

Patrick Catalano described the pattern of gestational weight gain, which is curved during the first two trimesters and then appears to be linear in the last trimester. Longitudinal studies of changes in fat mass show that as lean women (prepregnancy percentage of body fat of less than 25%) go through pregnancy, they tend to gain more fat compared with women who are obese (prepregnancy percentage body fat greater than 25%).

The IOM recommendations for weight gain in pregnancy reflect the curve of normal weight gain: very low at 0–10 weeks, 7 lb at 10–20 weeks, 10 lb at 20–30 weeks (this is when fat is accruing in the mother), and by 30–40 weeks the pace of weight gain should slow down. According to the average fetal growth curve, until about 28 weeks (the beginning of the third trimester), the average fetus weighs about 2 lb. From 28 weeks until term, there is a 5.5 lb increase in weight that reflects fetal growth. Taken together, about 7.7 lb of weight in late pregnancy is related to the fetus, placenta, and amniotic fluid, not specifically maternal weight. Now recommendations for weight gain are based on prepregnant BMI.

Weight gains outside the IOMs suggested ranges are associated with double the number of poor pregnancy outcomes as weight gains within the ranges.

**Association of Low Prepregnancy Weight with IUGR**

Many researchers have found that using a prepregnancy weight of less than 40 kg is a useful cut-off to predict women who will deliver LBW babies. Tripathi et al. (1987) found 60% of small-for-date Indian infants had mothers with prepregnancy weights less than 40 kg and a weight gain of less than 5 kg. Anderson (1989) estimated Indian women weighing less than 40 kg during the first 6 months postpartum had twice the risk of delivering LBW infants. In industrial countries the proportion of women who weigh less than 40 kg is very low. Gopalan (1985) estimated that only 1% of US women weigh less than 40 kg. Women in Africa probably have mean weights that are higher than women in Asia, in part because they are taller. Table 5 shows mean heights and weights of women from a number of countries.

**Energy Requirements During Pregnancy**

Energy requirements increase in pregnancy by about 12%. This is because of the increase in maternal body weight, an average 10–15% increase in basal metabolic rate and the energy requirements of the growing fetus and maternal physiological changes in pregnancy. Energy requirements are higher in later pregnancy but may be, at least partially, offset by mobilization of fat stored in early pregnancy.

Normally, women require 300 kcal more than their normal prepregnancy requirements during second and 450 kcal in third trimester and not during first trimester unless woman is underweight to start with she should gain about

| Table 5: Mean prepregnancy heights and weights of US and developing countries women |

*Note: Developing countries women from these studies are from low socioeconomic backgrounds while US women are from average socioeconomic backgrounds*
400 g/week. Women carrying twins should gain 35–45 pounds or approximately 150 kcal a day more than for a singleton pregnancy. Women pregnant with twins should gain approximately 4–6 pounds during the first trimester and 1.5 lb/week thereafter. This weight gain is associated with a decreased risk of preterm delivery and LBW infants. Only two studies have assessed weight gain in triplet pregnancies. A weight gain of 50 pounds in total, or approximately 1.5 lb/week throughout pregnancy, may be appropriate.

Energy deprivation in pregnancy leads to metabolic syndrome later on in life of the baby.

It is hypothesized that some chronic adult diseases originate in utero as a result of fetal adaptation to optimize survival. LBW has been associated with increased risk of later development of type 2 diabetes mellitus, heart disease, hypertension, obstructive lung disease, hypercholesterolemia and renal damage.

Maternal nutrition has therefore been the focus of considerable research over the last few years and because of strong epidemiological evidence of a relation between maternal nutritional status and birthweight, a number of intervention studies of nutritional supplementation during pregnancy have been carried out both in developing and developed countries. Interest has however been largely restricted to birthweight as an outcome, especially in populations with high prevalence of maternal undernutrition, LBW and perinatal mortality.

**Supplementation Trials**

During pregnancy, the fetus is solely dependent on maternal intake and nutritional stores, mostly fat, for its energy. The best methodological approach for assessing the effect of this factor on birthweight and more specifically on IUGR or prematurity is thus supplementation. Will an increase in food intake increase birthweight? Will the prevalence of LBW and IUGR/premature infants thus be decreased?

Provision of food does not necessarily lead to its consumption. Even if it is consumed, it may replace some of the usual diet or may be shared by the family, however supplementation had a positive effect on birthweight and IUGR.

The effect was greater the more malnourished the mother was before pregnancy. Nutritional supplementation during pregnancy was also shown to be associated with a reduction in the incidence of LBW in developing and developed populations. But regardless of methodological and practical differences, the effect of nutritional supplementation during pregnancy on birthweight has generally been modest, with an average increase of about 100 g.

One study showing a substantial effect was in the Gambia where daily supplements of groundnut based biscuits and vitamin fortified tea were distributed to pregnant women. The mean net increase of energy intake was 431 kcal per day. The resulting significant increase in birthweight was on average 120 g and the overall prevalence of LBW babies decreased significantly from 20% to 6%. There were however marked seasonal differences. Supplementation during the wet season ("hungry" season) led to a significant increase in birthweight of about 200 g and a decrease in the proportion of LBW from 23.7% to 7.5%; in the dry season supplementation had no effect (average increase of 2 g only).

Collated data sets suggested that if 100 kcal per day were supplemented throughout pregnancy, the risk of IUGR would be halved in mothers undernourished prior to pregnancy, but only reduced by one-fifth in well-nourished mothers.

- So women without overt malnutrition or in positive energy balance (Gambia dry season) obtain a limited benefit from nutritional supplementation during one pregnancy.
- Chronically malnourished mothers also supplemented during one pregnancy experience only a modest impact on birthweight of about 100 g.
- When women are however in negative energy balance, food supplementation produces a significant increase in birthweight as in the Gambia (230 g increase).
- The expectation of a dramatic recovery from generations of poverty and food scarcity in a short time is an overly optimistic proposition. It may be that the extra, yet prolonged, intake during pregnancies and lactation, rather than large amounts of supplementation during short periods of a given gestation produces the fetal growth effect.
- So all these studies point to the same thing that overall nutrition of women should be cared for and more so in the adolescents. Therefore, it is concluded that “unless future trials of energy and protein supplementation demonstrate clear reductions in risk for preterm birth, stillbirth, or neonatal death, or improvements in maternal health, focus should be shifted towards potentially more fruitful strategies for improving maternal and child health”.

**Interventions**

**Taking Prepregnant Weight**

Taking prepregnant weight is one way of finding out about the energy needs of a woman and if they are being met or not.

- In countries where it is difficult to reach women before conception in order to measure prepregnancy weight but where utilization of antenatal care programs is good, it is possible to obtain weight as a predictor of risk for LBW early in pregnancy up to the 13th week.
- Those women who are at risk for delivering LBW babies should be given appropriate nutrition education messages. If women are not able to eat more because of limited family resources or national supplies of food, every effort should be made, through the community, to educate family members to share and thus reduce the woman’s workload.
- In countries where women present for antenatal care only after the second or third trimester, a weight measurement
at 5th, 7th or 9th month should be obtained and compared with available references for maternal malnutrition.

- For women who are in their 5th or 7th month of pregnancy, appropriate measures to increase food intake or decrease workload are needed.
- If the woman is close to her delivery date, her weight should be measured, but the effectiveness of an intervention at this point to increase her weight is not great. Instead, if she is identified as “at risk” for delivering a LBW baby, procedures for referring her to a hospital before delivery should be reviewed with her in order to optimize the survival of the infant if it is born below 2.5 kg. Family members, traditional birth attendants, and other community members should be contacted to help make the referral process work smoothly.

### INDIA

Pune Maternal Nutritional Study in Maharashtra, India detailed the relationship between the anthropometry of 2,500 women living in six rural villages (measured every 3 months) and the anthropometry of the 633 full-term infants born to these women over a 3-year period. Mothers were short and underweight (mean height—1.52 m; weight—42 kg; BMI—18 kg/m²) and their infants’ birthweight averaged 2,648 g. When compared to measurements of mothers and infants born at Southampton, the Pune mothers and their infants were smaller in all dimensions. The height and weight of mothers from Pune were lower by almost two standard deviations, as was birthweight and placental weight. There was considerable variation, however, in the degree of deficit seen in the various components of the infants’ weight. Mid-arm and abdominal circumferences were dramatically lower by almost three standard deviations. In contrast, the skin fold thickness was only slightly reduced, and therefore subcutaneous fat was relatively spared. Head and length growth were also relatively preserved, although not to the same degree as fat. Thus, although these underweight babies were very thin in the sense that they had reduced soft tissue mass but they were actually relatively “fat”. It may be that fat is preserved as a neonatal survival mechanism. This neonatal phenotype, with reduced muscle mass and relatively increased fat, resembled the phenotype of the adult Indian patient with insulin resistance and diabetes—possibly that phenotype is laid down in utero.

It is thought that average consumption for females in most of rural India is less than they need. At ages 13–16, girls receive a higher percentage of their requirements than boys.

The possibility remains that girls aged 12 or younger are undernourished relative to boys of the same ages; since the National Nutrition Monitoring Bureau (NNMB) does not publish food consumption data separately by gender at these ages, the possibility cannot be tested with these data. However, the NNMB does provide anthropometry, a nutritional outcome indicator by gender for children. The prevalence of underweight for both boys and girls is very high, but there is no female disadvantage.

The bottom line is that gender differences in anthropometry shown for India do not support the notion of substantial dietary discrimination against females in early childhood.

But anthropometric evidence is available only for surviving children. India has been known as one of the few populations in which males outlive females, and this reversal of the usual female advantage in life expectancy has itself been interpreted as evidence of poorer nutrition for females. If this pattern persists, however, these comparisons of food consumption and nutritional status suggest that the explanation does not lie in dietary but rather in healthcare discrimination against females.

Females appear to receive less than a fair share of household food supplies in some regions of India. The data suggest, however, that dietary discrimination against females does not apply to the country as a whole—the situation varies from state to state, across age groups, and across social classes. The only reliable generalizations are that females who are neither pregnant nor lactating take in more relative to their requirements than do men, but that, during pregnancy and lactation, women are at a strong disadvantage relative to men.

The more favorable intakes of reproductive-aged women who are neither pregnant nor lactating argues against generalized discrimination and indicates that (Fig. 5):

- The nutritional needs during pregnancy, particularly while breastfeeding, are either not well understood by women and their households or (for other reasons, including poverty) not addressed. Not just caloric needs but also micronutrient requirements vary among individuals within the same household, especially growing children and pregnant and lactating women in comparison with most other adults.

![Fig. 5: Caloric adequacy of the diet by reproductive status, women ages 16–44, rural Punjab, India](source: Das Gupta, 1995)
• *Nutrition is not proper:* The effect of other possible contributing factors, such as consumption of foods that are not *sufficiently nutrient dense*, might be countered by greater awareness of increased need as well.

• *Energy expenditure is more:* Given that data on women’s energy expenditures are generally unavailable, we must understand that women’s caloric needs are underestimated by common methodologies. The energy needs of women whose domestic and/or paid work is particularly arduous are especially likely to be underestimated. Interventions that target these women and improve understanding of their increased needs may also be appropriate. During pregnancy 300 kcal/day are required more than routine requirement but if women are doing hard labor at home and at work outside then their requirements are more.

• *Less spacing:* Reproduction is a great nutritional stress and if they bear many children and if each child is breastfed for many months, they would be malnourished and is responsible for high incidence of LBW in India. Normally spacing should be minimum of 2 years. Similarly, inadequate intake during lactation may limit breast milk production and thus the growth of children for whom breast milk is an important part of the diet.

• *Discrimination:* Discrimination results from some members being deemed more valuable than others. Although some discrimination is a household-level manifestation of inequitarian attitudes pervasive in the society as a whole (e.g. women are less valuable than men, children are not fully human until after their first birthday, elderly people deserve higher honor. So the fact that average Indian woman weighs 25% less than American woman is because of food and not race, as they are fed last in the household from girlhood to womanhood.

**Gender Differences**

“Hypothesis of female nutritional disadvantage” has been proved to be wrong in Africa and it is concluded that the different roles of African (as compared with South Asian) women provide them with greater control over food and enable them to avoid nutritional deprivation for themselves and their children. Proportions of children underweight, stunted, or wasted appeared to be slightly higher for males than for females in four studies in Africa.

The conclusion, that females are discriminated against in access to food, rests disproportionately on studies from South Asia. The social status of women is especially low in South Asia. Their job opportunities are less and their income-earning potential is far lower than men’s. They take resources (labor and bride-price) out of their natal households. These factors explain why females are perceived as less valuable than males in the region. The female advantage in life expectancy that applies in most countries is reversed in Bangladesh, Bhutan, Nepal, and Pakistan. A female disadvantage in mortality is generally explained in terms of preferential treatment of males, with poorer nutrition for females often specifically cited as a likely part of such a pattern of discrimination. So nutritional discrimination is prevalent here.

Although average figures on calorie consumption have remained nearly unchanged since the mid-1970s, it is likely that household food security among the poorest social groups may have improved given the reported reductions in people living below the poverty line, and the fact that food consumption per caput of landless agricultural workers has risen. This is in line with reductions in underweight prevalence of 0.5 percentage points per year in preschool children.

Regionally, as well as the differences discussed with regard to agriculture, there are also highly significant state-by-state variations in many other nutrition-related variables discussed here, with many factors associated with nutritional problem areas clustering particularly in the states of Rajasthan, Uttar Pradesh, Madhya Pradesh, Bihar and Orissa. Anti-female bias in food provisioning, health care utilization, and general care may be particularly severe also in these northern states, and reflected in the regional differences in juvenile sex ratio. By contrast in Kerala where education and literacy rate is 100% there nutritional indices are highest for women.

Anemia is one of major factors responsible for maternal and fetal mortality and morbidity.

The Consequences of Iron Deficiency and Anemia in Pregnancy on Maternal Health, the Fetus and the Infant.

The health-conscious world community has come to realize that anemia, the majority of which is due to iron deficiency, has serious health and functional consequences.

It is widespread especially among tropical-low income populations and that most of its nutritional component is controllable with a very high benefit/cost ratio. Women of fertile age and pregnant-lactating as well as their infants and young children are particularly affected. The cut-off values for anemia among pregnant woman both non-smokers and smokers are shown in Tables 6 and 7.

In response to the overwhelming evidence to this effect, world authorities have agreed that a minimal goal is that by the end of this century, anemia in pregnant women must be reduced by one-third. The more aggressive groups believe that with new approaches for the control of iron deficiency a

Source: ¹From CDC (ICMR level is 11 g even in 2nd trimester)
reachable goal is to reduce iron deficiency anemia to overall levels below 10% in most populations.

Background

It is estimated that about 2,150 million people are iron deficient, and that this deficiency is severe enough to cause anemia in 1,200 million people globally. About 90% of all anemias have an iron deficiency component.

In the developing world, nearly half of the population is iron deficient. However the industrial world is not free from it: 11% of its population has iron deficiency.

High-risk of women of fertile age and pregnant women for incurring negative balance and iron deficiency is due to their increased iron needs because of menstruation and the substantial iron demands of pregnancy.

Median requirements of absorbed iron are estimated to be 1.36 and 1.73 mg per day among adult and teen-age menstruating females. However, 15% of adult menstruating women require more than 2.0 mg per day, and 5% require as much as 2.84 mg per day. The superimposition of menstrual losses and growth in menstruating teenage girls increases the demands for absorbed iron; 30% need to absorb more than 2.0 mg per day; 10% as much as 2.65 mg, and 5% 3.21 mg. These requirements are very difficult, if not impossible to satisfy even with good quality, iron-fortified diets.

Iron needs exhibit a marked increase during the second and especially during the third trimesters when median daily needs increase up to an average of 5.6 mg per day (that is, 4.1 mg above median prepregnancy needs). The approximate range would be 3.54 and 8.80 mg per day. This amount of absorbed iron needs cannot be met from food iron even if iron fortification is in place.

Factors affecting iron stores:
- Birth spacing favors iron nutrition among fertile-age women because each pregnancy has a high cost in terms of iron.
- However, the use of intrauterine devices almost doubles the iron menstrual loss.
- Women using anovulatory contraceptive methods reduce menstrual loss by almost half.
- Importantly, multiparous women tend to have greater menstrual losses that increase with parity.

Thus the importance of two factors: Prepregnancy iron reserves upon which to draw; and iron supplementation during pregnancy.

Iron deficiency during lactation is mostly a residual from that resulting from pregnancy and delivery and can be partially alleviated because of lactational amenorrhea. However, once menstruation returns, if lactation continues, iron requirements become higher to reach a median of about 1.81 mg/day. Dietary iron absorption in most populations of the developing world may not be sufficient to fulfill these needs.

In conclusion, iron deficiency during pregnancy is extremely common even among otherwise well-nourished populations because of the reasons reviewed above. The risk of iron deficiency in pregnancy and lactation begins with inadequate prepregnancy iron reserves among women of fertile age.

Folic Acid

Folic acid is required for the nucleic acid metabolism and for cell division and growth. Its deficiency causes megaloblastic anemia, neural tube defects, homocystanemia. It also prevents isolated cleft lip congenital anomalies.

Sources of folic acid: Green leafy vegetables, fruits, liver, kidney. RDA for adolescent girls is 500 µg/day.

Folate deficiency has also been documented during pregnancy, often leading to a combined iron-folate deficiency anemia, particularly among lower socioeconomic groups consuming mostly cereal-based diets (poor in folate) aggravated by:
- Prolonged cooking
- Food reheating of liquid preparations.
- Folate requirements double in the second half of pregnancy and are requirement increased by processes that involve hemolysis, such as malaria and hemoglobinopathies.

\(^{c}\) Hgb = hemoglobin
\(^{d}\) Hct = hematocrit
Changing Trends in Maternal Nutrition and Interventions

Malabsorption processes, common among tropical, low socioeconomic groups, impair folate absorption.

Hookworm infestation

Antifolate treatment as antiepileptic drugs can cause deficiency of folic acid.

Body reserves of folic acid are low.

Intake of goat’s milk which is low in folic acid could be cause of deficiency in rural areas.

Simple things like toilet and latrine facilities are not available in India.

Folic acid supplementation should be given to all adolescent girls preconceptionally. 500 microgram/day in low risk cases and in the high risk cases with H/O previous neural tube defect should be given in the dose of 5 mg/day. Minimum one month before conception. Iron and folate should be given together.

The overall proportion of women and pregnant women with below-standard hemoglobin is highest in South Asia and Africa, followed by Oceania, East Asia, and then Latin America (Fig. 6).

**SUPPLEMENTATION DURING PREGNANCY**

**Iodine Supplementation and Vitamin A Supplementation**

If mother is malnourished then she needs vitamin A supplementation.

Reasonably compelling evidence that nutrition interventions can prevent both infant (iodine supplementation) and maternal (vitamin A or β-carotene supplementation) deaths, is available from randomized trials, and informal analysis suggests that the cost-effectiveness of nutrition interventions would be comparable and in some cases markedly superior to several standard antenatal interventions. The impact of nutrition interventions could be profound. In Nepal vitamin A or β-carotene supplementation trials have been found to be effective and if they can be generalized to the wider developing world, as many as 200,000 maternal deaths per year might be preventable through this simple intervention. Likewise, if severe iodine deficiency were prevalent in one-half of the developing world, iodine supplementation might prevent over 100,000 neonatal and early childhood deaths annually, so iodine supplementation is being done in the form of iodized salt through India.

**Essential Fatty Acids**

Essential fatty acids, needed for neural tissue growth, in fetal tissue and blood correlate with weight and head circumference of the infant at birth (Hackney Hospital, 1991). More work is needed to determine if maternal fatty acid intake or status prior to conception or early in pregnancy is related to birthweight of her infant. DHA supplementation of 300 mg/day is required for retinal and cognitive development in fetus.

**Calcium**

The RDA for calcium is 1,200 mg/day. There is increase in 1,25-dihydroxyvitamin D levels (up to twice postpartum values), which leads to an increase in intestinal calcium absorption. The increase is so large that it exceeds the calcium needs and results in 2.5 times higher urinary calcium excretion during pregnancy than postpartum. If spacing of more than 2 years is there in two deliveries then depleted stores of calcium are replenished.

Multiparous women with poor calcium intake may develop clinical osteomalacia, and the fetal bone density may be similarly affected. Leg cramps during pregnancy may reflect altered calcium or magnesium metabolism.

Calcium supplementation of 1–2 g/day during pregnancy may reduce the risk of developing the hypertensive disorders of pregnancy, including pregnancy-induced hypertension, pre-eclampsia, and eclampsia.

**Zinc**

The RDA for zinc for pregnant women is 11 mg/d, 3 mg more than that allotted for the nonpregnant woman, although up to 40 mg/d is considered safe. The RDA is doubled for vegetarians because less zinc is absorbed with this diet. Without supplementation, zinc levels normally decrease during pregnancy, especially between weeks 14 and 35. Even with adequate supplementation, zinc levels decrease by 20–35% below prepregnancy levels, possibly the result of increases in blood volume, gestational estrogens, fetal needs, and the gestational decrease in albumin, which binds zinc.
Plasma zinc concentrations decline more precipitously when iron is supplemented orally as a result of competition for absorption by these two ions.

Populations at risk for zinc deficiency include:
- Vegetarians
- Alcoholics
- Smokers
- Teenagers
- Multigravidas with impaired intestinal absorption of zinc
- Women receiving diuretics
- Those with an acute stress response to infection or trauma.

Zinc deficiency has been associated with:
- Fetal intrauterine growth retardation
- Congenital malformations
- Premature and postmature births
- Low birthweight
- Perinatal death
- Abnormal delivery with dystocia and placenta abruption
- Gestational zinc deficiency can impair the development of the fetal immune system and impair neurogenesis and subsequent cognitive development, thereby influencing activity, attention, and neuropsychologic performance.

**PROBLEMS OF OVERWEIGHT**

There is a growing epidemic of obesity in the United States and all over world, in USA nearly one-third of all adults are classified as obese, and this proportion has dramatically increased during the last two decades. Women are leading the epidemic at a current prevalence rate of obesity of 33%. Given the environment of overweight and obesity in the United States, the implications of this epidemic for women of childbearing age are of a concern. Data from the March of Dimes Perinatal Data Center indicates that in 2003, 19.6% of US women of reproductive age were obese. Obesity in women can cause serious pregnancy-related complications.

Past efforts to advise women on weight for pregnancy (before, during, and after) have focused little on maternal obesity. Rather, most of the attention has been devoted to concerns about LBW deliveries in addition to other maternal and infant outcomes. Maternal Nutrition and the Course of Pregnancy, a 1970 report of the Food and Nutrition Board of the National Research Council (NRC), had laid stress on undernutrition.

**Obesity** is defined as having a BMI of 30 or greater (Fig. 7). Body mass index is a measure that appears throughout this report as the ratio of weight to height squared (kg/m² or lb/in² × 703) (National Heart, Lung, and Blood Institute, 1998).

**Maternal Weight Definitions (Figs 8 and 9)**
- **Prepregnancy weight:** A woman’s actual weight prior to pregnancy up to the point that pregnancy is identified (Table 8).
- **Prepregnancy weight gain:** A woman’s increase in weight from some prior time until pregnancy.
- **Gestational weight gain:** Amount of weight gained during the pregnancy.
Postpartum weight retention: Amount of weight gained during pregnancy (i.e. gestational weight gain) that the woman has at a given time point postpartum.

Postpartum weight gain: Weight that is gained following pregnancy.

Gestational Weight Gain

The recommendations of the 1990 IOM report specify weight gain ranges during pregnancy for singleton term births based on prepregnancy BMI (Table 9). National birth certificate data include maternal weight. However, data allow for a comparison between very low gestational weight gain groups (less than 15 lb) and very high gestational weight gain groups.

Influence of Pregnancy Overweight on Health

Initially it was maternal undernutrition and malnutrition that was problem so in 1974, the US Department of Agriculture established the Special Supplemental Food Program for Women, Infants, and Children to address the needs of women and children at nutritional risk, and in the intervening years it was realized that not undernutrition but obesity and overweight had also become a problem. Women were leading the epidemic of obesity at a current prevalence rate of obesity of 33%.

It was in 1990 the IOM report Nutrition During Pregnancy recommended guidelines for weight gain during pregnancy based on prepregnancy maternal BMI. Two other reports quickly followed—Nutrition During Lactation (1991) and Nutrition During Pregnancy and Lactation: An Implementation Guide (1992). By this time, the Maternal and Child Health Bureau of the US Department of Health and Human Services had also begun to address concerns about maternal weight gain. Since publication of the 1990 IOM recommendations for weight gain during pregnancy, tremendous changes have occurred in the demographic and epidemiological profile of women experiencing pregnancy. More women entering pregnancy are either overweight or obese, and more women are entering their pregnancies with chronic conditions that lead to increased morbidity during their postpregnancy years. High rates of overweight and obesity are especially common in minority populations that may be already at risk for poor maternal and child health outcomes.

Collectively, these trends have changed the direction of thinking about weight gain during pregnancy, particularly for women who are overweight, underweight, short in stature, or adolescents. In 1998 National Heart and Lung and Blood Institute (NHLBI) gave a revised BMI chart.

Nutrition in pregnancy in this millennium is very important now as the dietary habits of young women are changing in many societies and pregnant women are increasingly entering pregnancy as overweight. This increase in overweight was accompanied by a fivefold increase in gestational diabetes within 15 years in Norway, together with an unprecedented increase in the prevalence of large babies. This is accompanied by increasing risks of fetal malformations, damage to mother and child during parturition, and an increased risk of both obesity and type 2 diabetes in mother and the adolescent child. The prevalence of overweight girls is therefore a public health challenge with intergenerational implications.

Even in developing societies like India as they industrialize and urbanize, and as standards of living continue to rise, weight gain and obesity are beginning to pose a growing threat to the health of the citizens. According to the WHO’s global database, India has a preschool childhood obesity Prevalence of about 1%.

In 1998, 77% of the total number of deaths attributable to NCDs occurred in developing countries, and 85% of the disease burden was borne by low-income and middle-income countries.

The complex range of factors that interact to determine the nature and course of this epidemic needs to be understood in order to adopt preventive strategies to help developing countries.

A recent study of gestational weight gain and preeclampsia was done by Cedergren (2006). The adjusted odds ratio of developing pre-eclampsia for women with weight gains of less than 18 lb was substantially reduced for all women with a BMI more than 20 when compared with women who gained

between 18 lb and 35 lb. Women in all BMI groups who gained more than 35 lb were at greater risk of developing preeclampsia than women who gained between 18 lb and 35 lb. Even societies like India are dealing with problems of overweight.

**Gestational Diabetes Mellitus**

It is seen that the weight gain ratio (observed weight gain over the IOM recommended weight gain) was higher for women with gestational diabetes when compared statistically with women with normal glucose tolerance. The statistical likelihood of developing gestational diabetes was increased by both prepregnancy overweight and obesity status, while the interaction with weight gain during pregnancy was only marginal.

**Obesity Before Pregnancy Linked to Childhood Weight Problems**

“Prevention of childhood obesity needs to begin before a woman becomes pregnant”

—National Institutes of Health (NIH)

The study done by NIH showed a significant relationship between a mother’s weight prior to pregnancy and her child’s weight. If a woman was overweight before she became pregnant, her child was nearly three times more likely to be overweight by age 7 compared to a child whose mother was not overweight or obese, according to the study.

“Smoking during pregnancy causes a host of serious problems, there is growing body of evidence which suggests that smoking during pregnancy may be a key risk factor that increases a child’s chances of being overweight”.

Breastfeeding had a slight effect on weight at each measurement. As much as 5% fewer children who were breastfed were also overweight, compared to bottlefed babies.

**Fetal Origin of Disease Hypothesis**

The fetal origins of disease hypothesis states that susceptibility to adulthood cardiovascular disease (CVD), non-insulin-dependent diabetes mellitus (NIDDM), and the insulin resistance syndrome (IRS) is programmed in utero and is a response to fetal undernutrition. The hypothesis is also referred to as the thrifty phenotype hypothesis.

Over 15 years ago, Barker and colleagues published findings suggesting that fetal growth impairment is associated with CVD.

Numerous studies have now shown an inverse relationship between markers of fetal growth and the later development of CVD and IRS. Evidence is remarkably consistent for adult men and women.

In the Rancho Bernardo Study (depicted), women that had a LBW and were obese as adults had the highest prevalence of the metabolic syndrome (about 30%) (Fig. 10).

Investigators found that birthweight was inversely related to subsequent development of diabetes only among infants that were not breastfed. These studies suggest that the relationship between birthweight and the adult metabolic syndrome may be modified substantially by the presence of other risk factors, findings that are important for identifying opportunities for prevention.

Pregnancy, on the other hand, may be an optimal time to examine the fetal origins of disease hypothesis. Pregnancy can provoke conditions that are established or suspected precursors to the adult metabolic syndrome. For example, women who develop gestational diabetes are at an elevated risk for developing type 2 diabetes. Some studies suggest the risk of type 2 diabetes among women that have had gestational diabetes may be as high as 40%.

In a report from the Medical Birth Registry of Norway, women’s own birthweight was inversely related to their later risk for gestational diabetes (Fig. 11). The U-shaped curve presented here has been identified in other studies and is most likely attributed to the increased birthweight and increased diabetes risk of offspring of diabetic mothers.

These findings suggest that IUGR and not prematurity is the important predictor for later risk for gestational diabetes.

**Role of Nutrition in Pregnancy**

Human epidemiological studies and appropriately designed dietary interventions in animal models have provided considerable evidence to suggest that maternal nutritional imbalance and metabolic disturbances, during critical time windows of development, may have a persistent effect on the health of the offspring and may even be transmitted to the next generation.
Changing Trends in Maternal Nutrition and Interventions

Fig. 11: Risk for gestational diabetes by women’s own birthweight

Animal studies provide the best evidence to date. In rats, protein restrictive diets during pregnancy led to lower birthweight offspring and to higher blood pressure and reduced insulin secretion in adulthood (Fig. 12). Other studies of guinea pigs and sheep also have found that undernutrition during pregnancy altered insulin responses in offspring. These studies provide the best evidence that maternal nutrition can program the offspring physiologically in such a way as to influence disease susceptibility in adulthood.

Alternative Hypothesis, Genetic Influences

According to this hypothesis by Hattersley and Tooke fetal genetics would determine glucose sensing and insulin secretion by the fetal pancreas and thereby influence insulin mediated growth of the fetus. Defects in glucose sensing and insulin secretion would result in LBW, and lead to insulin resistance in adulthood.

Fig. 12: Animal studies

Fig. 13: Fetal insulin hypothesis

Dietary Consumption and Lifestyle Changes during the Nutrition Transition in India

Food balance data from the Food and Agriculture Organization (FAO) show that the change in energy intake in Asian countries has been small, but there have been large changes in consumption of animal products, sugars and fats. The net effect has been a marked shift in the diet with energy from fat (both animal and vegetable) increasing each year. Table 10 presents data from the District Nutrition Profiles Survey, which shows differences particularly in the intakes of vegetables and fruits, and fats and oils between urban and rural populations. The National Family Health Survey (NFHS) provides information on the consumption of specific and selected foods once a week at least and demonstrates, for instance, that the percentage of women consuming meat/chicken/fish once a week is higher in urban than rural locations and not related to standard of living index or educational status except for the illiterate group.

Intake of Fat in the Diet

It has been well documented that the intake of fat in the diet has been increasing in developing countries based on the
food balance analyses carried out by the FAO. Trends based on food balance sheet data show that the per capita supply of animal products has increased from 7.0 g in 1965 to 12.9 g in 1999, thus contributing almost twice the energy content (increased from 104 kcal/capita/day to 192 kcal/capita/day).

The differences in the dietary fat intake between rural and urban, and between lower and higher socioeconomic groups are largely due to large differences in the intakes of visible fats, except in the highest income group (Table 11) where much of it is from animal sources, with the invisible fat intake being similar among these groups. Computations also suggest that 25% of all available fat is consumed by the rural population, while 40% of all edible fat available in India is being consumed by 5% of the total population (i.e. 20% of the urban population that constitutes the “urban-rich”).

### Consumption of Fruits and Vegetables and Dietary Fiber

India has a prominent share in the global production of fruits and vegetables. However, much of this does not seem to be reflected in increases in the consumption of fruits and vegetables—perhaps largely the result of their production as cash crops for export and sale.

### Pollution of Food by Chemicals

There are several other factors likely to contribute to the emerging burden of chronic diseases in India for women and men and for pregnant women. Pollution of food sources by pesticides, chemical fertilizers and toxic contaminants is common in rapidly industrializing societies.

The specific objectives of nutrition in pregnancy are:
- To prevent malnutrition by promoting appropriate infant and young child feeding practices
- To reduce micronutrient malnutrition (particularly in children, adolescents and women of reproductive age)
- To promote healthy lifestyles and interventions for diet related NCDs. In India to reduce anemia just making people about wearing shoes in the fields and making availability of adequate latrine facilities would go a long way in eradicating anemia (only 18.9% of rural population has access to latrines as compared to 80.7% of urban population)
- To assist HIV/AIDS programs with training for reducing mother to child transmission and nutritional support for people living with HIV/AIDS.

### REACHING WOMEN

To improve nutrition in women we have to reach women but how to reach them for nutritional programs for their own good is not clear.
- Women’s nutrition supplementation studies in Guatemala and the Gambia have obtained good participation rates with measurable anthropometric results for women and children.
- A CARE feeding program in India found women more likely to participate if the food ration were ready to eat and women could pick it up on their way to the fields.
- A World Bank project in Indonesia induced women to eat better diets through a nutrition education program.

Behavioral trials determined that pregnant women were willing to increase their total food intake slightly and to eat more greens but were unwilling to eat extra protein or a great deal of additional food. Compliance with iron supplements was good and the negative side effects (of which they were forewarned) did not reduce compliance. This Indonesian work demonstrates that women can be motivated to improve their nutrition so long as it does not conflict with firmly held beliefs.

**Relations between Women’s Issues and Nutritional Issues**

These two issues are very closely intertwined.

- **Enhanced women’s status benefits nutrition:** Programs intended to improve nutritional conditions for women and their families can only be successful if problems of women are realized (Fig. 15).
  - Many women in poor societies are overworked by too many calls on their time and have too few resources to adequately cope with their circumstances. *Women’s fatigue* is now recognized as a social disease affecting not only their own health and well-being, but also their ability to care for the nutrition of their families.
  - Women’s access to productive resources that means if they start earning then increased income and more importantly increased control over it (both women’s income and total household income) would mean better nutrition.
  - Enhanced educational opportunities, social knowledge and decision-making power are prerequisites for more productivity.
  - Increased time available and devoted to productive tasks as well as enhanced efficiency of production.
  - In other words social, cultural and political empowerment of women must be regarded as prerequisites to solving any nutritional problems.

- **Improved nutrition benefits women’s issues:** Nutrition in pregnancy helps not only for well-being of mother and child but by concentrating on proper nutrition throughout the life cycle of a woman, she would have a much healthier life to pursue her multiple responsibilities for production, reproduction and care of family more efficiently, thereby in turn enhancing her social and economic status.

**Possible Interventions**

The over-riding need even in poor countries is for women empowerment: Equality of status in society and in the family, an equal role in making decisions. In viewing the changes in women’s position in industrialized countries at the start of this introduction, several factors were noted which both helped bring about these changes, and were themselves part of the improvement. In some very basic needs women in poor societies to this day lag far behind, notably in this context in their food security and access to health services.

**Education of Women**

Emphasis on education for women is so clearly correct that we can only reinforce this priority. It is well established that children of better educated women have better nutritional status, usually even allowing for income and other similar effects. Education here, rightly, means broad education, and is not just specific to health, nutrition, and child-rearing practices, essential as these are. A nutrition perspective would give major priority to women’s education, for its direct effects and its role in changing society for the better.

Mother’s education is strongly related to children’s malnutrition. According to NFHS, children of illiterate mothers are twice as likely to be undernourished or stunted as compared to literate mothers.

**Right to Decide about Reproduction**

Women’s ability to decide on the timing of their reproduction is similarly seen by many as fundamental human right. Here again, a nutritional view may help to reinforce this position, pointing out the convincing case that too frequent pregnancies, to too young mothers, lead to malnutrition and
increased maternal and child mortality; and that the reasons, although intuitive, are well understood.

**Time Management and Availability of Household Technologies**

Modern access to energy, as electrification, cooking gas is needed for environmental reasons and to save time and labor of women in collecting fuel.

**Availability of Better Health Services**

Serious deficiencies in health services for women contribute to the high mortality risk of childbearing, and their overall health problems. This not only has direct effects on women’s health, but contributes to the cycle of poverty. Moreover, children and the next generation are disadvantaged by LBW, malnutrition, and compromised caring capacity.

**CONCLUSION**

- There is strong epidemiological evidence of an association between maternal nutritional status, both during and prior to pregnancy (prepregnancy weight and weight gain during pregnancy), and birthweight and IUGR.
- Many trials of nutritional supplementation during pregnancy have been carried out, only to show a modest effect of supplementation on birthweight, even in undernourished women (about 100 g), and, according to one review, no long-term benefits to the child in terms of growth or neurocognitive development.
- Whether the supplementation trials were carried out at the right time during pregnancy still remains doubtful. Future supplementation during pregnancy is probably best targeted at nutritionally disadvantaged populations during all three trimesters of pregnancy.
- One of the major drawbacks of many of the studies carried out has been the failure to distinguish between IUGR and prematurity, and especially between stunted and wasted intrauterine growth retarded infants. Such distinctions would be most beneficial for future trials.
- More research is also needed on the effect of maternal nutrition during pregnancy on preterm delivery, and during consecutive pregnancies and prior to pregnancy.
- In the interim, maternal supplementation may be expected to have some benefit, but alone seems unlikely to make a major difference to LBW and child nutrition and it is overall improvement in women’s nutrition which is more important.
- Analyses using the Pregnancy Nutrition Surveillance System show that the risk of preterm delivery varied by both maternal prepregnancy BMI and gestational weight gain.
- Overweight before during and after pregnancy should be highlighted.

- More research should be done on “in utero origin of adult metabolic syndrome”
- Women should be empowered by education and job availability, time management appliances so that they can have better control on sources of nutrition and supply.

**Summary and Approaches for Alleviation of Maternal Nutritional Depletion**

Too young, too old, too many and too close—this is how UNFPA usefully summarizes the problem of frequent pregnancies and periods of lactation that contribute to nutritional depletion of the mother.

**FOR FUTURE CONSIDERATIONS**

**Adolescent Mothers**

Current consideration of pregnancy in adolescence and what guidance or interventions are appropriate for adolescent mothers with regard to obesity risk may need to be revisited. For example, the 1990 IOM recommendations suggest that very young adolescents gain up to the maximum of the range for their BMI. However, relative to older mothers, postpartum weight retention in young adolescents could be serious, as their lifetime weight retention risk may be far greater. For example, during the discussion, data presented about adolescent mothers suggested a relationship between adolescent growth during pregnancy and higher gestational weight gain and postpartum weight retention. In addition, many adolescent mothers (especially younger adolescents) would be expected to be gaining weight as part of typical development in the absence of a pregnancy. These biological factors, coupled with psychological and sociodemographic characteristics of adolescent mothers, make this a highly specialized population in need of focused attention.

**Obese and Morbidly Obese Women**

As obesity has increased generally, so has its incidence among women of childbearing age as well as among those who become pregnant. Obesity in women can cause serious pregnancy-related complications, but it can also be modified to improve birth outcomes. Additional attention is needed for the population of obese women who become pregnant.

A number of practical issues also arise, especially for morbidly obese patients and those who were morbidly obese but underwent bariatric surgery or similar procedures before becoming pregnant. For example, medical practice and equipment may need to be modified to accommodate very large women during pregnancy and especially during delivery. Finally, obese women with a range of medical conditions in addition to their pregnancy can face additional challenges in the management of their pregnancy.
Whole Person Approach (Fig. 16)

We should give equal attention to physical activity and not only to nutrition to have a whole person approach. It was noted that the 1990 IOM recommendations address weight only. In general, nutrition for pregnant and lactating women is currently focused on caloric intake, without specific attention paid to specific nutritional requirements or guidelines. Caloric intake and good nutrition intersect when women make specific food choices. In addition to nutrition guidance, weight control is also about physical activity. It is also important to understand the biological variability in women. Individual metabolism affects caloric and physical activity outcomes. More stress should be laid on exercise and physical activity during pregnancy.

BIBLIOGRAPHY

INTRODUCTION

We have progressed from an era of bed rest prescription to finally into the 21st century when we are talking about prescription of exercise and even dance therapy in pregnancy. Many women of childbearing age, 42% by one estimate, report exercising during pregnancy and many strongly desire to continue to do so.

The traditional medical advice has been for exercising women to reduce their habitual levels of exertion in pregnancy and for nonexercising women to refrain from initiating strenuous exercise programs. This advice was based on concerns that exercise could affect early and late pregnancy outcomes by increasing core body temperature during embryogenesis, increasing the risk of congenital anomalies, and shifting oxygenated blood and energy substrates to maternal skeletal muscle away from the developing fetus, leading to disturbances in growth.

Early studies focusing on hard physical work combined with undernutrition and on forced exercise in laboratory animals tend to support these concerns. Other concerns included:
- The risk of maternal musculoskeletal injury due to changes in posture and center of gravity
- Fetoplacental injury due to blunt trauma
- Stress effects from sudden motions

But recent investigations, focusing on both aerobic and strength-conditioning exercise regimens in pregnancy have shown:
- No increase in early pregnancy loss
- Late pregnancy complications
- Abnormal fetal growth
- Adverse neonatal outcomes

So, the new evidence suggests that previous recommendations have been overly conservative.

COCHRANE REVIEW

Aerobic exercise is physical activity that stimulates a person’s breathing and blood circulation. The review of 11 trials, involving 472 pregnant women, found that pregnant women, who engage in vigorous exercise at least two to three times per week, improve (or maintain) their physical fitness, and there is some evidence that these women have pregnancies of the same length as those who maintain their usual activities. There is too little evidence from trials to show whether there are other effects on the woman and her baby. The trials reviewed included noncontact exercises such as swimming, static cycling and general floor exercise programs. Most of the trials were small and of insufficient methodological quality. Therefore, larger, better trials are needed before confident recommendations can be made about the benefits and risk of aerobic exercise in pregnancy (The Cochrane Database of Systematic Reviews, 2007, Issue 1).

Low-impact aerobic dance, compared with walking at similar heart rates, results in a lower maternal metabolic rate and increases the transient stress on the fetus but this is just a small study.

So pregnancy should not be a state of confinement and pregnant women should be encouraged to engage in physical
activity, move about, work and exercise, and eat healthy. Exercise has minimal risks and many confirmed benefits for most women.

So in the light of all these and so many other studies and along with support of guidelines from the American College of Obstetricians and Gynecologists, the Royal College of Obstetricians and Gynaecologists (RCOG), [Society of Obstetricians and Gynaecologists of Canada, Canadian Society for Exercise Physiology (SOGC/CSEP)] the latest suggestions are:

- All women should be encouraged to participate in aerobic and strength-conditioning exercise as part of a healthy lifestyle during their pregnancy (II-1, 2B)
- Reasonable goals of aerobic conditioning in pregnancy should be to maintain a good fitness level throughout pregnancy without trying to reach peak fitness level or training for athletic competition (II-1, 2 C)
- Women should choose activities that will minimize the risk of loss of balance and fetal trauma (III-C)
- Women should be advised that adverse pregnancy or neonatal outcomes are not increased for exercising women (II-1, 2B)
- Initiation of pelvic floor exercises in the immediate postpartum period may reduce the risk of future urinary incontinence (II-1C)
- Women should be advised that moderate exercise during lactation does not affect the quantity or composition of breast milk or have an impact on fetal growth (I-A)
- Exertion at altitudes up to 6,000 feet appears to be safe. Engaging in physical activities at higher altitudes carries a risk of hypoxemia.

**WHAT ARE THE BENEFITS OF EXERCISE DURING PREGNANCY?**

Childbirth is among the most physically stressful challenges a woman ever faces. Regular exercise during pregnancy:

- Strengthens muscles needed for labor and delivery
- Helps reduce backaches, constipation, bloating, and swelling
- Improves posture
- Gives energy and improves mood
- Lessens some of the discomforts of pregnancy
- Helps one feel less tired and sleep better; strength and stamina are increased.

**Benefits to the Infants**

- Infants have less body fat at birth
- Infants are less cranky, have a reduction in the incidence of infant colic
- Greater neurodevelopmental scores in oral language and motor areas (tested at age 5).

**RISKS OF SEDENTARY LIFESTYLE IN PREGNANCY**

If women are prescribed bed rest and do not do regular physical activity or exercise, then they are prone to following complications in pregnancy:

- Loss of muscular tone and strength
- Cardiovascular fitness is decreased
- Excessive maternal weight gain
- Higher risk of gestational diabetes
- Higher risk of pregnancy-induced hypertension
- Development of varicose veins
- Development of deep vein thrombosis
- A higher incidence of physical complaints such as dyspnea or low back pain
- Poor psychological adjustment to the physical changes of pregnancy.

**WHEN AND HOW TO START AN EXERCISE PROGRAM?**

- The best time to initiate an exercise program is in the second trimester, when the nausea, vomiting, and profound fatigue of the first trimester have passed and before the physical limitations of the third trimester begin. Concerns about the teratogenic effect of high core body temperatures in the early first trimester have not been demonstrated in studies of exercising women.
- Women who have been exercising prior to pregnancy may continue their exercise regimens throughout pregnancy using the guidelines outlined below (II-1, 2B).

**Conditions Requiring Medical Supervision while Undertaking Exercise in Pregnancy**

- Cardiac disease
- Restrictive lung disease
- Persistent bleeding in the second and third trimesters
- Preeclampsia or pregnancy-induced hypertension
- Preterm labor (previous/present)
- Intrauterine growth restriction
- Cervical weakness/cerclage
- Placenta previa after 26 weeks
- Preterm prelabor rupture of membranes
- Heavy smoker (more than 20 cigarettes a day)
- Orthopedic limitations
- Poorly controlled hypertension
- Extremely sedentary lifestyle
- Unevaluated maternal cardiac arrhythmia
- Chronic bronchitis
- Multiple gestation (individualized and medically supervised)
Maternal Exercises, Yoga and Dance Therapy

CHAPTER

5

Maternal Exercises,
Yoga
and Dance Therapy

39

Poorly controlled thyroid disease
Morbid obesity (body mass index greater than 40)
Malnutrition or eating disorder
Poorly controlled diabetes mellitus
Poorly controlled seizures
Anemia (hemoglobin less than 100 g/L).

Healthcare professionals should use their professional judgment as to what extent and duration, exercise should be undertaken in the above circumstances.

Warning Signs to Terminate Exercise
If any of the following symptoms appear during exercise then patient should immediately stop exercise and seek medical attention:

- Excessive shortness of breath
- Chest pain or palpitations
- Presyncope or dizziness
- Painful uterine contractions or preterm labor
- Leakage of amniotic fluid
- Vaginal bleeding
- Excessive fatigue
- Abdominal pain, particularly in back or pubic area
- Pelvic girdle pain
- Reduced fetal movement
- Dyspnea before exertion
- Headache
- Muscle weakness
- Calf pain or swelling.

WHICH MUSCLE GROUPS ARE MOST IMPORTANT TO EXERCISE?

In addition to heart, the three muscle groups, one should concentrate on during pregnancy are the muscles of abdomen, back, and pelvis.

- Strengthening abdominal muscles will make it easier to support the increasing weight of baby. One will also be able to push with more strength and more effectively during the second stage of labor.
- Strengthening back muscles and doing exercises to improve posture will reduce the strain of pregnancy on lower back. It will help prevent discomfort caused by poor posture.
- Strengthening pelvic muscles will allow vagina to dilate more easily during delivery. This will help prevent urinary problems later on as stress incontinence.

Exercise should be made a part of daily life. Daily tasks can double the exercise sessions if one does the following:

- Tighten abdominal muscles when standing or sitting
- Squat when lifting anything, whether it is light or heavy
- Rotate feet and ankles anytime your feet are elevated
- Check posture each time you pass a mirror

Pilates During Pregnancy
The benefits that have been associated with exercise and pregnancy are based on research done on cardiovascular exercise (aerobic). There has been minimal research done on the independent benefits of pilates. Because the base of pilates is “core” training, we believe that pilates can be a beneficial adjunct to any exercise program. The pregnant woman should make sure she is working with a pilates instructor who is trained in prenatal exercise.

Yoga Exercises in Pregnancy
The benefits that have been associated with exercise and pregnancy are based on research done on cardiovascular exercise (aerobic). There has been minimal research done on the independent benefits of Yoga. We believe that Yoga can be a beneficial adjunct to any exercise program. For the pregnant woman, she should make sure she is working with a Yoga instructor who is trained in prenatal exercise. Pregnant women should avoid exercise in extreme environmental conditions, i.e. hot Yoga should be avoided and avoid inverted positions or positions that require spending long periods of...
time on your back. As always, pregnant women should not stretch past their prepregnancy range of motion.

**Tae-Bo During Pregnancy**

Tae-Bo, like any other exercise that includes a cardio, flexibility and strength component, is a good adjunct to training program while pregnant. One has to be careful with fast, uncontrolled movements and jumping or high bouncing activities. Smaller range of motion should be used when exercising and fast kicks and high leg thrusts should be avoided.

**PROTOCOL OF EXERCISE**

In general, exercise prescriptions or exercise protocols are defined by type, intensity, duration, and frequency of exercise. In addition to these four factors, it is important to consider the likes and dislikes of the individual (i.e. working out at home, in gyms, outside, biking, walking, swimming—swimming is a great activity) to perform while pregnant. This activity uses all of the major muscle groups in the body. The water also supports your extra pregnancy weight and decreases added strain on joints (Figs 1 and 2).

Each day a pregnant woman should take the time to relax and stretch, controlling breathing (inhaling and exhaling) throughout the entire stretch, while avoiding bouncing. At the beginning or end of each exercise session, one should take the time to stretch all muscles. Pregnant women should especially focus on calves and legs to avoid cramping.

**DURATION OF EXERCISE**

When prescribing exercise duration; it is important to also consider the environment during exercise. It is important to not exercise in excess of 45 minutes in an environment which does not provide proper ventilation or air conditioning, dangers of thermoregulation can occur. Proper hydration throughout exercise is important remember. Thirst is not a sign of rehydration, it is a sign you are already dehydrated, drink plenty of fluids throughout the day, as well as during exercise sessions are must (Fig. 3).

**INTENSITY OF EXERCISE DURING PREGNANCY**

The development of an exercise program requires individual adaptation. Prior to advising exercise, physician should assess:
- Fitness status
- Current athletic or exercise activities
- Individual goals of exercise

Most guidelines advocate a maximal heart rate of 60–70% for women who were sedentary prior to pregnancy and the upper range of 60–90% of maximal heart rate for women wishing to maintain fitness during pregnancy (Table 1).

Women who were active prior to gestation can continue their exercise routine as long as there are no contraindications. Women beginning an exercise program during pregnancy should start with short durations, 15 minutes a day, and add 5 minutes every week or 2 weeks they are exercising, until they are achieving 30 minutes of moderate activity a day on most days of the week. Health effects can still be accomplished when exercise is broken up throughout the day. Less is better than nothing at all. Starting to add activity into daily schedule when health of the pregnant woman as well as that of the unborn child is at the forefront of the mind is a perfect style.
of healthy living and staying “fit for two”, and has a higher chance of becoming a real lifestyle change.

Other measures of exercise intensity include the “talk test” and a visual rating of perceived exertion. When using the “talk test”, exercise takes place at a comfortable intensity, allowing the woman to maintain a conversation during exercise. A method of measuring perceived exertion is the Borg’s scale of perceived exertion (Table 2). This approach seems to be effective as, when exercise is self-paced, most pregnant women will voluntarily reduce their exercise intensity as pregnancy progresses. For moderate exercise during pregnancy, ratings of perceived exertion should be 12–14 (somewhat hard) on the 6–20 scale.

**Mode of Activity**

- Although there is no established upper level of safe exercise intensity, regular exercisers before pregnancy should be able to engage in high intensity exercise programs, such as jogging and aerobics, with no adverse effect to mother or fetus. Women who have attained a high level of fitness through exercise prior to pregnancy should exercise caution in engaging in higher levels of fitness activities during pregnancy. They should also expect a decline in overall activity and fitness levels as pregnancy progresses.

  - It is suggested that a warm up and cool down period be included in any exercise regimen.
  - There is less evidence on strength conditioning, weight training and stretching exercises such as Yoga and pilates in pregnancy. Considering complementary and alternative therapies in pregnancy, limited evidence currently exists and attention needs to be given for undertaking high-quality randomized controlled trials in these areas.
  - Women should not scuba dive in pregnancy, as the fetus is not protected for decompression sickness and gas embolism.
  - Women are cautioned about the potential for loss of balance and fetal trauma if they participate in horseback riding, downhill skiing, ice hockey, gymnastics and cycling during pregnancy.
  - Women who have gestational diabetes mellitus must take particular precautions with exercise including monitoring blood glucose, regulating meal times, scheduling rest periods and carefully tracking fetal activity and uterine contractions.
  - No adverse effects on the fetus have been reported to occur during water exercise in pregnancy. The physiology of water exercise offers some compensation for the physiological changes of exercise on land that may beneficially affect pregnancy. If a woman is exercising in water (as in aquanatal classes) the water temperature should not exceed 32°C. 35°C is the recommended maximum while using a hydrotherapy pool.

*Fig. 3: Duration of exercise*
**Frequency of Exercise**

Frequency is a relatively simple factor in exercise prescriptions. When there are no contraindications with exercise for a female during pregnancy they should try to achieve the recommendations stated by the American College of Sports Medicine and the Centers for Disease Control and Prevention—achieving 30 minutes a day of exercise on most if not all days of the week.

**Tips for the First Trimester**

Dance as you normally would, but keep a few precautions in mind:

- Remember to warm up beforehand to prepare your joints and muscles for exercise, which also builds up your heart rate slowly. Skipping a warm-up could strain ligaments and joints, leading to injury.
- The intensity of dancing should be adjusted according to how one feels. A good rule of thumb—slow down if one cannot comfortably carry on a conversation.
- Keep workout at low-impact by keeping one foot on the floor at all times, substituting marching or stepping side to side for jumps.

**Tips for the Second and Third Trimesters**

Center of gravity shifts as abdomen enlarges, so pay extra attention to balance.

In Africa, the childbearing woman is said to be the key to the universe. She holds the future generation within her womb, as you do. African dance steals you away from the discomfort you may be feeling and makes you gloriously aware of the miracle happening within you. Simply, naturally, you begin to appreciate the fullness of your body, and the life that you encompass.

**Tribal Effect**

Finally, beyond the physical benefits of dancing during pregnancy, there is also that great thing called having a good time with other women. And it goes beyond just laughing it up while shaking your belly with other moms-to-be. Tribal effect of dancing together has a positive impact on the mother’s experience of pregnancy and helps reduce stress. Cowlin says, “These are psychosocial benefits of group physical activity.” Sounds like another great reason to start dancing.

**Belly Dancing Related to Birth Process**

The connection between belly dancing and birth is not a new one. Work has been done, noticed and unnoticed to bring the dance to the attention of birth educators. The link was forged as early as 1965 by Carolina Varga-Dinicu known as Morocco. She compared childbirth education taught at Mount Sinai Hospital in New York and major books like *Natural Childbirth* by Dr Frederick W Goodrich to her dance movements as she performed them.

In 1976, Gigi Groth Devitt, a member of Birth Day in Boston, collaborated with the dancer Barbara Brandt and demonstrated among other things, that Lamaze and this dance are based on the same method of muscle isolation. Around that same time, Edith Maxwell stressed the importance of movement during labor and showed how the movements of this dance help in *moving the baby down* the birth canal.

**COMPETITIVE ATHLETES AND PREGNANCY**

Elite athletes who continue to train during pregnancy require supervision by an obstetric care provider with the knowledge of the impact of strenuous exercise on maternal and fetal outcomes. All pregnant athletes must be made aware of proper hydration, the additional nutritional requirements of pregnancy and exercise, and the dangers of heat stress. Routine obstetric evaluation must be strongly recommended. Additional evaluation to assess fetal growth and well-being may be appropriate if clinically indicated. Although risks are minimal with moderation, even healthy active women should be examined periodically to assess the effect of their exercise programs on the developing fetus and their regimen should be adjusted and discontinued if necessary. Competitive athletes can expect to experience a reduction in their performance during pregnancy.

**Dance and Music**

Dance is a form of aerobic activity as it involves rhythmic movements of various groups of muscles. So whatever form of dance is performed, if it is not of high impact aerobic type and the performer enjoys the music and motion, then it is relaxing and good fitness and balance exercise.

**Benefits of Dancing During Pregnancy**

Dancing is a fantastic and fun exercise during pregnancy. Not only one gets the thrill of moving body to music one loves, but it will keep one flexible while toning muscles. One can get an aerobic workout from any fast-paced dance, or stretch and maintain muscle tone when holding positions in ballet. For maximum benefit, dance for at least 20 minutes three times a week, whether it’s in living room or in class. In addition to teaching women how to relax better, dance through pregnancy classes teach women to strengthen their core in preparation for the intense work of labor. Students learn to “strengthen against resistance in motions that help prepare for labor and birth, including Kegel’s, abdominal hiss/compress exercises and C-curves, as well as the abdominal core strength, upper back strength, and leg strength in dance-related movements”. These are treated as an integrated and flowing choreography.
In 1983, Wendy Buonaventura published a book, *Belly Dancing*, where she outlined the role of the dance throughout history in many cultures. She showed that the dance has always been a part of the birth process. The most exact comparative work was done by Morgana, in 1981. She compared specific movements of the dance to the phases of birth and the motion of the emergence of the baby. She has shown that the dance movements exercise all the birth muscles, and the rhythms, in fact, match the birth process. Her work leaves the impression that the dance could be none other than a birth dance.

Belly dance helps in strengthening muscles in the following motions:

- The circle is a sacred shape and is the very foundation of the dance. Moving the heart in a circle *strengthens and flexes the upper abdominals*.
- Moving the hips in a circle masses the internal organs, including the pelvic floor, and also *conditions the lower abdominals*.
- *Tension* is released by moving the wrists, shoulders and ankles in circles, and by rotating the spine in small circles.
- *Accents* introduce a faster rhythm and they are the power of the dance because they provide an outlet for inner impulses. Hip thrusting teaches control and builds concentration for focusing on one body part while the rest relaxes.
- *Shimmies*, all the different varieties, are the endurance of the dance. They require intense concentration and control of deep inner muscles. They loosen the back and hips and allow the focus to shift from pain to movement.
- *Body undulations are the flexibility of the dance*. The movements mirror how a woman’s body stretches to allow a baby to grow, and at the same time prepares the birth muscles for the task. Undulations also require concentration and focus, mainly because the muscles that need to be activated are unfamiliar to most people.

All of these qualities—relaxation, focus, endurance, and flexibility are needed in the birth process. Belly dance can be done standing, kneeling, lying down or walking. Lastly, belly dancing while giving birth means movement in general is encouraged while trying to give birth. It gives the power back to the process and allows women to find their way through the pain and fear of giving birth.

**Music Therapy During Pregnancy**

Although music therapy in healthcare settings is not new, bringing live music to the bedside is a new way of extending the caring tradition of nursing practice. Bedside musical care is consistent with a philosophy of holistic nursing practice and can be used during pregnancy, childbirth, and in neonatal care. It is defined as live music at the bedside, which is part of a treatment plan to foster integrity, well-being, and health for varied populations across the lifespan.

---

**THE ACTUAL PLAN**

**First Trimester**

**Warm-Up**
Walking 8 minutes at a slow to moderate pace is enough to allow your heart rate to begin to rise.

**Aerobic Activity**
This can be 20–40 minutes of walking at a brisk pace, biking on a stationary bicycle, swimming, aerobics, etc. Remember if exercise is new, start with a shorter duration and slowly add to the amount of time one is exercising until one is able to achieve at least 30 minutes a day. Make sure one is comfortable with the intensity, one should still be able to carry on a conversation, and not use heart rate as an indication of intensity; Borg’s rating of perceived exertion can be used.

**Cool-Down**
Walking, biking, etc. for 5 minutes at a slower pace or lower resistance. This should be followed by 5–10 minutes of stretching. This can include all the stretches. Each stretch should be held for 10–30 seconds at a point of mild discomfort (in the muscle being stretched, if there is pain in the abdomen choose another stretch), one can repeat each stretch 2–3 times, with proper breathing.

**Sample Lifting Workout (Fig. 4)**
Remember days before lifting weights one should still start with a warm-up, enough to get the blood flowing to muscles. It is recommended to perform a total body workout 2–3 days a week.

**Workout 1**

**Upper Body**
- Dumbbell row 2 sets × 12 repetitions
- Incline dumbbell bench press 2 sets × 12 repetitions
- Side raise 2 × 12
- Bicep curl 1 × 12
- Tricep extension 1 × 12.

**Lower Body**
- Ball squat 3 × 15
- Leg extension 3 × 15 each leg (hold each for a count of three)
- Back bridge: 30.

**Workout 2**

**Upper Body**
- Pulldown 2 × 12
**Second Trimester**

**Warm-Up**

Same as first trimester.

**Aerobic Activity**

It is never too late to start. If this is where you are beginning, start slow and slowly increase in duration or intensity.

- **Machine chest press** $2 \times 12$ (remember dumb-bell exercises can be substituted)
- **Front raise** $1 \times 12$
- **Bicep curl** $1 \times 12$
- **Tricep pressdown** $1 \times 12$

**Lower Body**

- **Ball squat** $2 \times 20$
- **Leg extension** $2 \times 20$ each leg (hold each for a count of three)
Continue to use the rating of perceived exertion to measure your intensity, not your heart rate (heart rate is altered due to the physiologic changes of pregnancy and is not an accurate measure of exertion).

**Cool-Down**

Same as first trimester.

**Lifting Workout**

Same as first trimester. Remember that one does not want to increase the intensity in such a manner that lifting weights cause one to hold breath (thus, increasing blood pressure). Continue exercising at a moderate intensity. If certain exercises are uncomfortable then the workout should be altered in such a way that one is able to enjoy the exercises and perform them with no discomfort.

**Third Trimester**

**Warm-Up**

Same as first trimester.

**Aerobic Activity**

Use own body as a judge. Remember one should be able to carry on a conversation while working. Good communication with physician must be kept.

**Cool-Down**

Same as first trimester.

**Lifting Workout**

Same as first trimester. Remember avoid standing in one position for extensive periods of time, so move around. Supine position exercises should be avoided. Physicians should be consulted regularly. Exercise should be continued as long as one feels comfortable. Patient herself is the real judge of her body.

**INSTRUCTIONS FOR PATIENT EDUCATION ON STEPS OF EXERCISES: BODY WEIGHT STRETCHES**

**Upper Body**

**Shoulder Stretch**

- Hold raised elbow above chest
- Pull arm across body with opposite arm
- Keep shoulders square ahead

- Apply enough pressure to feel a stretch in shoulder
- Hold for 10–20 seconds, repeat with both arms (Fig. 5).

**Triceps Stretch**

- Bend your arm and pull it behind your head
- Reach as far down your back with the bent arm
- Apply pressure downward on your elbow with the opposite arm
- You should feel a stretch in the triceps, shoulder, and the middle of your back
- Hold for 10–20 seconds, repeat with both arms (Fig. 6).

**Fig. 5: Shoulder stretch**

**Fig. 6: Triceps stretch**
Seated Shoulder Stretch

- In a seated position, place arms straight behind you and reach as far as you can.
- Lean back slightly until a stretch is felt in the front of your shoulder.
- Hold for 10–20 seconds (Fig. 7).

Butterfly Stretch

- Sit on the ground, with back up tall, pull your heels as close to your body as possible.
- Remain sitting up tall and push out on your knees with your elbows.
- Do not bounce and hold for 10–30 seconds (Fig. 9).

Lower Body

Feet Together (Seated)

- Sitting on the ground, extend your legs out, keeping your feet together, and reach your hands toward your toes, grab your calves if you are unable to reach your toes.
- Relax your lower back to achieve an adequate stretch.
- Do not bounce and hold for 10–30 seconds (Fig. 8).

Modified Hurdler

- Sitting on the ground, bring a heel to the opposite leg.
- Keep leg straight and flat on the ground.
- Reach with both hands toward your toes. If you cannot reach your toes, reach as far as you can and grab under your leg.
- Do not bounce and hold for 10–30 seconds, repeat with other leg (Fig. 10).
STRENGTH TRAINING EXERCISES  
(INSTRUCTION FOR THE PATIENTS IN STEP OF EXERCISES)

Upper Body

Dumb-bell Row

- Place the opposite hand on the bench for support. Place one foot slightly behind your hips on the ground with your knee slightly bent; place the other knee on the bench below your hips. Your back should remain flat and your head should stay focused straight ahead (Fig. 11).
- Grasp the dumb-bell in one hand. Begin the exercise with the weight arm-length away. Slowly pull the weight to the chest while squeezing your shoulder blades together.
- Think of the hand as a hook and pull the weight using your upper back muscles. Pause the weight at the chest and slowly lower the weight to the starting position.
- Do not swing your arm to achieve the movement. Remain under control throughout the full range of motion.
- Perform desired repetitions on one arm then perform the same number on the opposite arm.

Pull Down

- Grasp the bar with an underhand grip (palms facing your body). Make sure your hands are evenly spaced and approximately shoulder width apart.
- Begin the exercise with arms straight. Pull the bar to your chest, attempting to pull the elbows down and backward.
- Remain sitting up tall, with your eyes focused straight ahead.
- Pause the bar at your chest before extending the arms back to the starting position.

Incline Dumb-bell Press

- Sit on a bench (with the back pad at a 45° angle), with your feet flat on the floor.
- Hold a dumb-bell in each hand. Start with the weight at chest level. With palms facing each other, slowly press the dumb-bells straight up.
- Pause with arms fully extended and then slowly lower the weights to starting position.
- When performing this exercise have a spotter standing directly behind you.

Machine Press

- Depending on where you are working out will depend on what type of machine is available.
- Adjust the seat so the handles hit you in the middle of your chest. Press the machine lever arms straight out.
- Pause with arms straight, then slowly lower the weight back to the starting position.
- A machine is a good alternative when there is no one available to spot dumb-bell exercises.

Side Raise

- Begin with arms hanging by the side of the body, thumbs pointed straight ahead.
- Keeping your arms straight, but not locked at the elbow, raise the arms out to your sides until the hands are parallel with your shoulders.
- Pause at the top and lower the weight.
- Do not swing the weight at the top. Remain under control throughout the full range of motion. Stand up tall throughout the exercise, never arching your back (Fig. 12).
Bicep Curl

- Stand tall (or sit on a bench). Hold the dumbbells with your arms fully extended. Slowly curl your arms at the elbows bringing the weights up to your chin.
- Lower the weights under control to the starting position.
- Do not swing or arch your back during the movement (Figs 13A and B).

Tricep Extension

- Sit on the edge of bench
- Hold a dumbbell in your hand
- Elbow straight and upper arm along with head
- Flex at the elbow taking your lower arm at the back of head, do not move elbow
- Bring to starting position. Do 10 repetitions and repeat with opposite arm (Figs 14A and B).

Lower Body

Ball Squat

- Your feet should be shoulder width apart, and a ball (Swiss ball, stability ball, or even a basketball can be used) should be placed between your lower back and the wall.
- You can hold dumbbells or plates in each hand at the sides of your body, or the exercise can be performed with just your body weight.
- Place your feet on the ground at a distance so when you squat your knees will not go over your toes.
- Slowly lower your body to where your upper leg is parallel to the ground (or as low as you can go, not exceeding parallel to the ground). Pause, and then slowly raise your body back to starting position.
- Keep your chest tall throughout the motion. The ball will roll during the exercise and will end at the middle of your back (when in the squat position).
- Do not allow your knees to turn in, but keep them in line with your toes (Fig. 15).
Maternal Exercises, Yoga and Dance Therapy

CHAPTER 5

Maternal Exercises, Yoga and Dance Therapy

Fig. 15: Ball squat

Leg Extension

- Start with both knees and both hands on the ground, with your back flat and your head looking straight ahead.
- Raise one leg up to the point where it forms a straight line from your head to your toes.
- Perform slowly, hold for a three count and then return to the start position, perform desired number of repetitions and then switch legs (Fig. 16).

Back Bridge

Lie on your back on the ground. Place your feet flat on the ground. Raise your hips up, squeezing your buttocks. Hold for a designated amount of time and then relax. This may not be able to be performed in the later stages of pregnancy (Fig. 17).

Pelvic Tilt

This can be performed on the ground or standing against a wall. When lying on the ground with your feet flat you will feel a small curve in the low of your back (the same is felt when standing against a wall). Push your belly button toward the ground or wall, controlling your pelvis. Hold for a count of three and then relax, repeat for the desired number of repetitions (Fig. 18).

POSTPARTUM EXERCISE

Benefits of postpartum exercise include improved cardiovascular fitness, facilitated weight loss, raised positive mood, reduced anxiety and depression and more energy. Postpartum women are able to participate in moderate physical activity without compromise to infant breast milk acceptance or infant growth. By strengthening the pelvic floor muscles, the risk of urinary stress incontinence may be reduced.

Current recommendations suggest that, if pregnancy and delivery are uncomplicated, a mild exercise program consisting of walking, pelvic floor exercises and stretching may begin immediately. However, if delivery was complicated or was by lower segment cesarean section, a medical caregiver should be consulted before resuming prepregnancy levels of physical activity, usually after the first postpartum check-up at 6–8 weeks. Women need to return to prepregnancy exercise levels gradually, not resuming high impact activity too soon.

EXERCISE DURING BREASTFEEDING

Breastfeeding is the best method of providing optimal nutrition, immunology-based protection, and emotional nurturing for the growth and development of infants. Therefore, exercise frequency and intensity should not interfere with a mother’s ability to breastfeed. Although exercise does not negatively affect milk production or composition, lactic acid has been shown to be increased in the breast milk of women exercising at maximal intensity, but not in those exercising at moderate levels. Controversy exists as to whether this short-term increase in lactic acid makes the breast milk less palatable to the nursing infant. Mothers who
find their baby does not feed as well right after exercising may consider feeding the baby right before exercising (which may also make the breasts more comfortable during exercise), postponing feeding until 1 hour after exercising, or expressing milk prior to exercising to be used after exercising. The growth of breastfeeding babies of exercising women is normal, even for the infants whose mothers are losing weight as part of their exercise regimen.

EXERCISES FOR THE WORKING WOMEN

Sometimes working women are working double shift, i.e. doing both the house hold and office work. In that case, they need exercises for keeping strength and tone of the muscles and stretching exercises for providing complete range of motion of joints and relaxation is also important and these exercises should be integrated into their routine lifestyle.

Women who are working should also make sure that their circulation is maintained. Those doing desk job should be circulating around, i.e. after an hour or so they should walk around. Their back should be straight and properly supported. They can use foot rests to prop up their feet. Stretching exercises for the shoulders and upper back can be done in between. Diet should be nutritious.

Labor class workers employed in field jobs or as laborers in construction industry should do work where risk of injury is minimum and in the afternoon rest should be given for 1–1.5 hours. Calorie intake should be increased as per demands of physical work involved.

CONCLUSION

A review of the evidence suggests that, in most cases, exercise is safe for both mother and fetus during pregnancy and women should therefore be encouraged to initiate or continue exercise to derive the health benefits associated with such activities.

(Chapter updated by Mohita Pengoria)

Genetic Counseling for Obstetricians

GENETIC COUNSELING

Genetic counseling is defined as "the process by which patients or relatives at risk of a disorder are advised of the consequences of the disorder, the probability of developing and transmitting it, and ways in which this can be ameliorated". An accurate diagnosis of the disorder is very essential for any genetic counseling. A thorough knowledge of the manner, in which a particular disorder is inherited, is essential when giving advice to members of a family regarding the likelihood of their being affected, or having affected children.

PRENATAL DIAGNOSTIC TECHNIQUES

Prenatal diagnostic techniques for diagnosing congenital and genetic disorders in utero have proved to be a major advance in medical genetics and have altered the outlook for families at risk of having an affected child with a serious and untreatable disorder. In this specific setting of "New Obstetrics", Obstetricians should learn to apply basic principles of "Genetic Counseling". The Human Genome Project is an international effort to discern the complete genetic make-up of human beings. The isolation and characterization of genes offer tremendous opportunities for disease detection, diagnosis, screening, prevention and counseling. Advances in genetic research are occurring simultaneously with the development of new techniques for prenatal genetic testing. The obstetric community needs to participate actively in the debate surrounding the ethical and legal implications of the Human Genome Project. Since the science of genetics has become increasingly important in the practice of Medicine, all Obstetricians need to know the basic fundamentals of molecular biological techniques currently used in deoxyribonucleic acid (DNA) diagnostic tests; the practical and clinical aspects of genetics relevant to the discipline. Reproductive genetic counseling offers options to patients related to testing (prenatal or carrier) and child bearing. The focus of the counseling is often on decision making by the patient, including accepting the consequences of the choice(s), as it is the patient and the family who have to live with the decision. The strategy of population screening, offering genetic counseling, prenatal diagnosis (PND) and termination of affected pregnancy has been successfully applied worldwide. Common fetal sampling techniques in utero include chorionic villus sampling (CVS), amniocentesis and fetal blood sampling. Appropriate laboratory analysis is applied for diagnosis, where karyotyping is mainly for chromosome abnormalities and polymerase chain reaction (PCR) is for single gene disorders. Several modern molecular techniques are useful for identification of defects in single genes. Preimplantation genetic diagnosis is an advanced alternative giving the couple the chance to start a pregnancy ensuring that the baby is free from the genetic disease.

Aims of Genetic Counseling

Aims of genetic counseling are to help the individual or family to:
- Comprehend the medical facts including the diagnosis, probable course of the disorder and the available management
- Appreciate the way heredity contributes to the disorder and the risk of recurrence in the specified relatives
- Understand the alternatives for dealing with the risk of recurrence
• Choose a course of action which seems to them appropriate in view of their risk, their family goals, and their ethical and religious standards and act in accordance with the decision.

• Make the best possible adjustments to the disorder in an affected family member and/or to the risk of recurrence of that disorder.

Basic Background and Terms

Basic background and terms with special connotations must be introduced and defined at this point:

• The principles of inheritance were discovered in 1865 by Mendel and were subsequently “rediscovered” around 1900 by others. In 1902, Sutton and Boveri first suggested that chromosomes served as the physical basis of inheritance. DNA is the hereditary matter of all living organisms except certain viruses. Subsequently, several types of ribonucleic acid (RNA) were shown to be required to translate the information inherent in the genes. In 1953, Watson and Crick proposed that DNA existed in the form of a double helix; this structural configuration helped explain how DNA could replicate.

• Genes are recognized by the physical characteristics or traits determined by them.

• Trait is a gene—determined characteristic.

• Pedigree is information about families with an inherited condition stored in a family tree which is a shorthand reference of data.

• Inherited condition is defined when several members are affected in different generations, or in the same generation, or an affected member can pass on the condition to his or her next generation.

• Genotype describes the genetic constitution of an individual.

• Phenotype refers to the observable expression of a specific trait, or characteristics that can be visible or biochemically detectable, e.g. blonde hair, blood group A.

• Dominant trait implies that a single copy of the allele is enough for the condition to be expressed. It is seen in both the heterozygotes and homozygotes.

• Recessive trait is one, which is expressed only when two copies or doses of the gene are present.

• Codominant traits are those in which the effects of both alleles may be seen in the heterozygote, e.g. AB blood group.

• X- or Y-linked refers to genes having loci on either the X- or Y- chromosomes.

• Genetic heterogeneity refers to several genes having one effect, e.g. deafness, microcephaly, etc.

• Consultand, proband: The person seeking counseling is called “consultand or counselee” and the index case or affected child is called “proband.”

CONGENITAL MALFORMATIONS AND GENETIC DISEASE INHERITANCE

They can be grouped into: (1) Mendelian inheritance, (2) chromosomal defects and (3) multifactorial or polygenic disorders.

Mendelian Inheritance

Mendelian inheritance involves gene mutation and the risk of recurrence which will depend on the type of inheritance. The usual patterns of transmission are autosomal dominant (AD), autosomal recessive (AR), X-linked dominant, X-linked recessive (XLR) and Y-linked. There are 5,710 human single gene disorders listed in McKusick’s catalogue “Mendelian inheritance in man” (McKusick VA, 1992) which is a valuable ready reference for counseling. Over half are inherited in an AD fashion, about one-third as recessive and one-tenth as X-linked.

In an AR disorder, risk of recurrence is 25% for the sibling. In AD disorder, the risk of recurrence for the sibling is 50% if one of the parents is affected. If it is a sporadic case (new mutation), risk of recurrence in sibling is very low but gonadal mosaicism cannot be ruled out. In XLR disorders, risk of recurrence for boys is 50% whereas females usually do not manifest.

Structural Malformations

Single gene defects causing malformations that can be detected by ultrasound can be either isolated or multiple/syndromic (Table 1). Recurrence risk for the next pregnancy varies depending upon the inheritance pattern.

Chromosomal Defects

Majority of chromosomal disorders have been associated with mental retardation. For example, Down syndrome (DS), Edward syndrome (trisomy 18), Patau syndrome (trisomy 13), etc. In all de novo numerical and structural chromosomal abnormalities, there is a low risk of recurrence (<1%). Risk is higher if either of the parents is carrying a balanced translocation.

Structural Malformations

Five to seven percent of fetuses with single malformation and 15–30% of fetuses with multiple malformations have chromosomal abnormalities. A number of abnormalities detected on ultrasound examination are indicative of aneuploidies like trisomy 21, 18, 13 and 45, X. Of these, nuchal translucency (NT) is of utmost importance. Presence of other soft markers like pyelectasis, short femur, echogenic bowel, sandal gap, etc. in isolation is markers of less
significance. Presence of these findings with other ultrasound abnormalities is an indication for fetal chromosomal analysis.

**Multifactorial or Polygenic Disorders**

These constitute majority of birth defects. These are mostly isolated or non-syndromic malformations. These can be as follows:
- Cardiac, e.g. atrial septal defect (ASD), ventricular septal defect (VSD), tetralogy of Fallot (TOF), patent ductus arteriosus (PDA)
- Central nervous system (CNS), e.g. anencephaly, spina bifida
- Genitourinary, e.g. renal agenesis
- Others, e.g. talipes, cleft lip (CL)/cleft palate (CP).

### NEURAL TUBE DEFECT

Neural tube defect (NTD) is one of the common malformations. The reported incidence in India varies from 0.5–11 per 1,000 live births. Most cases are straightforward and involve an isolated NTD, either anencephaly or spina bifida, or both. Care is needed to ensure that one is dealing with a primary NTD or NTD is a part of syndrome, teratogenic exposure or chromosomal anomaly. Vertebral anomalies and hydronephrosis are commonly seen in isolated NTDs. It can be uniformly fatal as in anencephaly, iniencephaly, acrania; total craniospinal rachisis or prognosis may be variable depending upon the types of defect. In open defect 5 years survival is 36% and 82% are severely handicapped whereas in closed defect 5 years survival is 60%; but 33% are severely handicapped.

**Etiology**

Neural tube defect can either occur as an isolated defect or as part of a syndrome, as described below.

#### Syndromic Defect

- **Chromosomal:** 10% (22qdel, trisomy 13, 18, triploidy, unbalanced translocation)
- **Autosomal recessive:** Meckel-Gruber syndromes, Jarcho-Levin syndrome, Robert syndrome, Walker-Warburg syndrome.

**Isolated Defect**

- **Genetic defect:**
  - Polygenic: Predisposing genes not known
  - Probable association with C677T polymorphism in methylenetetrahydrofolate reductase (MTHFR) gene
- **Environmental defect:**
  - Drugs: Valproate, alcohol, folic acid antagonists
  - Maternal diabetes mellitus.

### ROLE OF A GENETIC COUNSELOR

Genetic counseling involves an attempt by one or more appropriately trained persons ideally by a team of
professionals that may include physician, genetic counselor, cytogeneticist/biochemical geneticist, social worker, psychologist and preferably a religious leader. In one study, among 145 patients evaluated, 38% (n = 55) had additional genetic risk factors detected by trained genetic counselor (p = 0.01). The maternal demographics and characteristics did not differ between the two groups. The practice of referring high-risk obstetric patients for genetic counseling improves the detection of identifiable genetic risk factors.4

**INDICATIONS OF PRENATAL DIAGNOSIS AND GENETIC COUNSELING**3-7

Common indications for genetic counseling in obstetric practice are as follows:

- Advanced maternal age (AMA)
- Positive maternal serum screen
- Abnormal fetal ultrasound
- Previous child with a de novo chromosomal abnormality or presence of structural chromosomal abnormality in one of the parent
- Family history of a genetic disorder that can be diagnosed or ruled out by DNA or biochemical analysis, like thalassemia, spinal muscular atrophy, hemophilia, congenital deafness, Gaucher disease or other inborn errors of metabolism
- History of unexplained mental retardation/dysmorphism/multiple malformations/lethal skeletal dysplasia/unexplained stillbirths (SB)/neonatal or infantile deaths with or without congenital malformations in previous child or in the family
- Recurrent pregnancy loss/SB
- Infertility
- Maternal disease
- Teratogen exposure
- Parental concern.

Analysis of genetic counseling and antenatal diagnostic services offered by a genetics’ unit in a women’s hospital undertaken to identify genetic needs of the Obstetrician-Gynecologist, and findings derived from a genetic questionnaire administered routinely to obstetric registrants showed that certain well-defined indications for genetic referral were identified, allowing specific educational objectives to be formulated. Potential chromosomal abnormalities constitute the most common indications for referral, particularly AMA and repetitive abortions. A wide range of Mendelian and polygenic/multifactorial disorders was encountered, albeit many individually rare. This suggests that the Obstetrician-Gynecologist should become familiar with principles of these modes of inheritance. However, educational objectives need not stress specific details of rare disorders but rather should emphasize the relatively few disorders that the Obstetrician-Gynecologist is likely to encounter.8

**GENETIC COUNSELING CASE MANAGEMENT PROCEDURE**5

This procedure involves the following:

- **Information gathering:**
  - History with particular emphasis on pedigree construction and analysis (Annexures 1 and 2)
  - Detailed clinical examination
  - Diagnosis
  - Investigations of family members
- **Information giving:**
  - Nature and course of disorder
  - Recurrence risk
  - Possible treatment
  - Availability of further or future testing
  - Prenatal diagnosis if possible
  - Decision making
  - Referral to other specialists, health agencies, support groups
- **Follow-up:**
  - Continuing clinical assessment, especially if no diagnosis
  - Psychological support.

**Pedigree Charting (Annexures 1 and 2)**

Pedigree charting is an important part of history taking. There is tremendous utility of the prenatal three-generation pedigree in assessment of the obstetric patient’s primary medical risks. In a case series out of 250 charts of patients referred for amniocentesis on the basis of AMA, a total of 40 patients (16%) were at significantly increased risk for a primary care disorder. Thirty-eight patients (15.2%) were at increased risk for medical conditions for which early screening, detection and/or interventions are established. For the AMA population, formal genetic risk assessment performed prior to amniocentesis can be beneficial in primary care risk assessment.9 A three-generation pedigree is superior to a questionnaire in genetic risk assessment, the questionnaire may not be sufficiently sensitive to serve independently as an adequate genetic screen or risk assessment tool and may not influence subsequent fetal evaluation.10

**GENETIC COUNSELING AND GOALS OF PRENATAL DIAGNOSIS**

The purpose of PND is not simply to detect abnormalities and perform termination of pregnancy (TOP) when the fetus is found to have a defect. Rather, the goals of PND are:

- To provide a range of informed choice to couples at risk of having a child with an abnormality
- To provide reassurance and to reduce anxiety, especially among high-risk groups
• To allow couples at risk of having a child with a specific birth defect, who might otherwise forego having children, to begin a pregnancy with the knowledge that the presence or absence of the disorder in the fetus can be confirmed by testing

• To allow couples the option of appropriate management for the impending birth of a child with a genetic disorder in terms of psychological preparation, pregnancy/delivery management and postnatal care

• To enable prenatal treatment of the affected fetus.

### Annexure 1: Common pedigree symbols, definitions and abbreviations

**Instructions:**
- Key should contain all information relevant to interpretation of pedigree (e.g. define shading)
- For clinical (non-published) pedigrees include:
  a. Family names/initals, when appropriate
  b. Name and title of person recording pedigree
  c. Historian (person relaying family history information)
  d. Date of intake/update.
- Recommended order of information placed below symbol (below to lower right, if necessary):
  a. Age/date of birth or age at death
  b. Evaluation
  c. Pedigree number (e.g. I-1, I-2, I-3).

Abbreviations: ECT, ectopic pregnancy; TAb, threatened abortion; VTOP, voluntary termination of pregnancy; Ab, abortion
The generally accepted guidelines for eligibility of pregnant women for PND by amniocentesis or CVS are based on the evidence that the risk for fetal abnormality is at least as great as the risk of miscarriage from the procedure itself.

**Need for Genetic Studies**
- To plan mode of delivery
- To plan postnatal management
- To prognosticate likelihood of postnatal survival
- To decide on medical termination of pregnancy (MTP).

**Pre-test Counseling**
Preliminary genetic counseling of candidates who desire PND usually deals with the following:
- The risk that the fetus is affected
- The nature and probable consequences of the specific problem
- The risks and limitations of the procedures to be used
- The time required before a report can be issued
- The possible need for a repeat procedure in the event of a failed attempt
- The limitation of a test (in view of laboratory error).

Comparison of 275 consecutive patients referred for genetic counseling and amniocentesis on the basis of AMA were compared with charts of 103 consecutive patients referred for an abnormal maternal serum alpha-fetoprotein (MSAFP) finding. In 35.6% of pedigrees evaluated, a significant genetic risk was discovered during genetic consultation that had not been noted by the referring physician. Furthermore, 9.8% of AMA patients and 10.7% of patients with abnormal MSAFP results underwent additional genetic testing or screening on the basis of genetic counseling. Data supports the importance of genetic counseling before amniocentesis in more accurately ascertaining genetic risk and in maximizing the benefits of genetic evaluation of patients seemingly at low risk for other genetic diseases.

**GENETIC COUNSELING AND PRENATAL DIAGNOSIS FOR GENETIC DISORDERS**

**Mendelian Disorders**
For most of the common genetic single gene disorders, either enzyme based or molecular diagnosis is available, though facilities for diagnosis of all disorders are not available, in India. PND is possible by using the same techniques on fetal tissues—chorionic villus (CV) biopsy or amniotic fluid examination.

**X-Linked Disorders**
In pregnancies at high risk for X-linked disorder, fetal sexing offers the possibility of determining whether the fetus is indeed at risk. However, in most disorders direct molecular PND of an affected male is now possible, and even where it is not, linked DNA markers can often be used. First-trimester fetal sexing, using both DNA and cytogenetic methods, is now feasible with CVS. Where a woman is only a possible carrier, it is vital to estimate the risk before fetal sexing is undertaken and to use methods of carrier detection where applicable. The most successful approach to PND is where no prenatal procedure is required at all, because the carrier state is excluded. As far as possible, this should be approached as a planned procedure.

**Inborn Errors of Metabolism**
More than 100 metabolic disorders like organic acidemias and aminoacidemia’s (phenylketonuria, maple syrup urine disease), carbohydrate disorders (galactosemia), cholesterol metabolism disorder (X-Linked ichthyosis), lysosomal disorder (Hurler syndrome), peroxisomal disorder (chondrodysplasia punctata and Zellweger syndrome), etc. can be diagnosed prenatally in CV tissue or cultured amniocytes or directly by assay of a substance in amniotic fluid, like in methylmalonic acidemias, 21-hydroxylase form of congenital adrenal hyperplasia and congenital nephrosis by raised alpha-fetoprotein (AFP) levels. The following points need to be remembered in PND of a metabolic disorder:
- Most metabolic disorders are rare in the general population, but have a high recurrence risk of 25% (1 in 4) for most being AR in nature. Risks for other relatives are rarely high enough to warrant undertaking PND
- Whenever possible, biochemical assay on direct CV tissue as opposed to cultured tissue is preferred, to avoid delay and misinterpretation of results due to expansion in culture of the number of contaminating maternal cells
- Because each condition is rare, the experience of the laboratory performing the prenatal diagnostic testing is very important, thus referral to specialized centers is often desirable
- Wherever possible, samples from the affected individual should be studied alongside those at risk.

**Chromosomal Disorders**
Prenatal screening for common chromosomal disorders has good sensitivity using maternal serum biochemical markers and ultrasonography (USG). Definitive diagnosis can be provided by chromosomal studies on amniotic fluid, CV biopsy or cord blood sample.

**Ultrasound Scanning in Prenatal Diagnosis**
Fetal anomaly scan is done at 11–14 weeks and 18–20 weeks to look at the major malformations and soft markers.

**First-trimester Scan**
It has been shown that around this time there is strong association between chromosomal abnormality and
abnormal accumulation of fluid behind baby’s neck, referred to as increased “fetal NT”. This applies both to DS and other autosomal trisomy syndromes like trisomy 13 and 18. By combining information on maternal age with results of fetal NT and thickness measurements, it is possible to detect approximately 80% of fetuses with trisomy 21, if invasive testing is offered to the 5% of pregnant women with the highest risk.

**Second-trimester Scan**

Significant sonographic findings are seen in nearly all fetuses with trisomy 13 and in about 77–100% of trisomy 18. Current sonographic criteria can identify 65–75% of fetuses with DS with a false positive rate of 4–15% in second trimester. Presence of multiple abnormalities raises the risk of any chromosomal abnormality to 35% (Table 2). With the combined usage of sonographic markers for DS and maternal serum screening, the vast majority of fetuses with DS could be potentially detected.

**Multifactorial or Polygenic Disorders**

Counseling and risk of recurrence in these disorders is based on empiric risk figures, and many anatomic anomalies indicate a heritable tendency. PND is possible in some defects using fetal USG. After diagnosis of any malformation on fetal anomaly scan, one should apply the knowledge of various genetic disorders and syndromes to provide appropriate nondirective genetic counseling and management. Table 3 shows risk of recurrence of some common malformations. Counseling in multifactorial disorders is to be done carefully, as there is a close overlap between hereditary and non-hereditary disorders. PND of major malformation is possible and the risk prediction can be calculated more accurately. There are guidelines which can help the at-risk families to plan the family or can be of great help in premarriage counseling.

risks of DS and offered amniocentesis; however, uptake of amniocentesis varies greatly between countries and region, and has been considerably affected by the development of second-trimester maternal serum screening. Availability of first-trimester screen results in more AMA women having early prenatal genetic counseling and choosing some form of genetic testing.13

**Translocation Down Syndrome**

Translocation DS comprises only 5% of all cases of DS. The risks for the offspring of balanced carriers varies from 2.5% to 10% for father and mother as a carrier, respectively for 14/21 and 21/22 translocations and 100% for 21/21 translocation. So precise type can be established from chromosomal analysis of index case, and the relatives at risk should be investigated using blood before pregnancy occurs. Where the parents of a child with translocation DS are both chromosomally normal, the risk of further affected child is also low, probably similar to that for trisomic DS and other autosomal trisomies, i.e. less than 1%.

**Trisomic Down Syndrome and Other Autosomal Trisomies**

Trisomic DS and other autosomal trisomies carry low recurrence risk with the exception of very rare families, possibly because of predisposition to nondisjunction or gonadal mosaicism. In practice, most couples with previous affected child do elect for PND in subsequent pregnancy, with full knowledge of the procedural risks and low probability of recurrence. For other relatives of a child with isolated trisomic DS, there is no evidence of an increased risk in their offspring.

**Structural Malformations**

**Antenatal Screening for Neural Tube Defect**

**Maternal serum screening:** Maternal serum AFP levels are measured at 16–18 weeks of gestation. A cut-off greater than 2.5 multiple of median (MOM) detects greater than 90% cases of anencephaly and 80% cases of spina bifida cystica. Though the specificity of the test is not very high, being increased in abortion, twin pregnancy, exomphalos, etc. yet it has been implemented widely and has led to a striking decline in the incidence of open NTD.

**Ultrasound screening:** Anencephaly is detectable at 10–12 weeks of gestation; spina bifida is detectable at 16 weeks onwards; large defects may be visible earlier.

**Prevention:** Folic acid supplementation (4 mg/day) started 2 months before to 3 months after conception (periconceptional) prevents recurrence in about 72% of cases. Primary prevention (about 50%) by use of 0.4 mg of folic acid periconceptionally has also been recommended.

**Malformation with Uncertain Prognosis**

This is a challenge to the counselor as well as a dilemma for the family. Some of the malformations with uncertain prognosis are ventriculomegaly, meningocoele, omphalocoele, multicystic kidneys, hydronephrosis, urinary bladder obstruction, cystic adenomatoid lung malformation, diaphragmatic hernia, cardiac defects, cyst/calcification inside abdomen, mild limb shortening.

**Maternal Serum Screening for Down Syndrome**

Down syndrome is the most common cause of mental retardation with a prevalence of about 1 in every 800–1,000 births.14,15 The majority of cases of DS occur due to an extra chromosome 21. The spontaneous loss rate of fetuses with DS is approximately 30–43% between the time of CVS in the later first trimester and term, and 18–23% between the time of amniocentesis in mid-to-early second trimester and term. Knowledge of the loss rate of affected fetus is important for counseling prospective parents and for assessing the available screening methods at varying times of gestation.

**First-trimester Screening**

Although many markers have been studied in the first trimester, two robust markers suggested are beta-human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein A (PAPP-A). Fetal β-hCG (Fβ-hCG) has been found to be elevated with the median MOM values of 2.15, almost similar to the second trimester. PAPP-A values are low with the median MOM of around 0.45–0.51, this alteration is not seen in the second trimester. Based on the available data, the detection rates using these two markers varies between 60% and 67% with a false positive rate of 5%. Detection of trisomy 18 and 13 has also been reported by first-trimester screening with good detection rates.

**Second-trimester Screening**

**Triple Test/Multimarker Screening**

It includes AFP, human chorionic gonadotropin (hCG) and unconjugated estriol (uE3) estimation in maternal serum. Expressed in MOM values, maternal serum AFP and uE3 are reduced by 25%, whereas hCG levels are doubled in pregnancies with DS. None of these parameters alone gives absolute discrimination but taken together they provide a means of modifying a woman’s prior age-related risk to give an overall probability that the unborn is unaffected. When this probability exceeds 1 in 270 or 1 in 250 (USA and UK respectively) invasive testing in the form of amniocentesis or placental biopsy or cordocentesis is offered. At a risk cut-off level of 1:270, 59% of pregnancies with DS and 5% of unaffected pregnancies are designated as screen positive.
Use of level II ultrasound improves the detection rate to 69% at a false positive rate of 5%. Thus, all cases of DS cannot be diagnosed by triple screening.

Until a decade ago, amniocentesis was reserved for women of greater than or equal to 35 years of age, who produced approximately 20% of fetal DS population. With the advent of maternal serum screening, an additional 30–40% of fetuses with DS became identifiable, still leaving a large cohort of patients who carried fetuses with DS but who were not candidate for invasive testing. Disadvantages of second-trimester screening is that it creates more anxiety and late intervention if fetus is affected posing risk to mother.

**Quadruple Test**

Addition of a fourth biochemical marker, inhibin-A, (increased in DS pregnancies) in the second-trimester screen, increases the sensitivity of screening for DS from 60% to 75%.

**Factors affecting levels of maternal serum markers:** There are numerous factors which can affect levels of maternal serum markers. Many screening programs take these into account while calculating risks. These factors include maternal weight (tendency to decrease due to greater blood volume), number of fetuses, smoking, ethnicity, gravidity and parity, previous screening results, assisted reproduction, pregnancy complications and diabetes (lower levels). Most programs usually include correction for maternal weight and diabetic status.

**OSCAR clinic:** The one stop clinic for assessment of risk for fetal anomaly (OSCAR) is prevalent in western countries. It means that in 1-hour single visit, both the biochemical (FIβ-hCG, PAPP-A) and USG (NT + crown rump length + anomaly scan) is carried out between 11 weeks and 14 weeks. It has a predictive value of 86%.

In conclusion, biochemical screening for aneuploidies has many advantages over age-based screening alone: (1) sensitivity and specificity are improved; (2) chromosomal abnormalities other than DS and trisomy 18 are also detected; and (3) prevention can be offered to younger mothers also. However difficult counseling situations and delayed confirmation of fetal chromosomal abnormalities can create problems. This can be taken care off with the help of proper pre-test and post-test counseling.

**ROLE OF OBSTETRICIANS IN MANAGEMENT OF PATIENTS WITH GENETIC DISORDER AND ANTENATAL DETECTION OF MALFORMATION**

Flow charts 1 and 2 depict management of patients with genetic disorders and antenatal detection of malformation, respectively.

**SPECIAL PROBLEMS IN GENETIC COUNSELING**

In some of the situations, especially known AR and AD disorders, counseling and presentation of risks is relatively straightforward based on the principles of Mendelian inheritance. However, in the presence of reduced penetrance, delayed onset and genetic heterogeneity (a disorder caused by more than one genetic mechanism), extending into different modes of inheritance, the counseling becomes more difficult. There are several situations that can pose problems while counseling.

**PRE-TEST AND POST-TEST COUNSELING FOR BIOCHEMICAL SCREENING**

Before offering antenatal biochemical screening, understanding of some basics to interpret these tests and provide effective genetic counseling are required:

- The tests should be performed at specified gestation (e.g. between 15 weeks and 20 weeks for second-trimester screen and between 11 weeks and 14 weeks for first-trimester screening)
- The values change with gestational age. In the second trimester, AFP and uE3 increase with gestational age while hCG decreases. Ideally each testing laboratory should have its own standards of normal values at different gestations
- Values are expressed in MOM for easier understanding and comparison between laboratories
- The detection rates are not 100% even with multiple markers (as discussed earlier and these are screening tests not diagnostic tests)
- Pre-test and post-test counseling are the biggest challenges and should always be done religiously and cautiously. The most important points to emphasize are—a positive test does not mean that the fetus has DS and a negative test does not rule out DS. Table 1 gives a check list for pre-test and post-test counseling. The screening tests are done to relieve the anxiety, but in most situations if done without counseling can make the couple very anxious. In India as the tests have been introduced recently and pre-test and post-test counseling is inadequate; it creates more confusion than solving the problems in many situations in authors’ experience. It is imperative that the clinicians ordering the test should clearly understand the interpretation
- The interpretation is usually given after calculating the risk by entering the data in available software programs. The usual cut-off risk is taken as 1 in 250. Any values having more risk than this are "screen positive", e.g. if the triple test interpretation gives result of 1 in 500 it means that if 500 women had these test values one will have a baby with DS. This is usually compared with a pre-test risk-based on maternal age.
Consanguinity

Consanguinity implies relationship between blood relatives who have at least one common ancestor, not more remote than a great-great grandparent. In Indian scenario, uncle-niece relationship (second degree) is the most common. The absolute risk of abnormal offspring (SB, neonatal death and congenital malformation) for marriages between first cousins is 3–5%, about double the overall background risk of 2–3% for offspring of unrelated individuals. Similarly, the probability that first cousins will have a child with an AR disorder is approximately 3%, although the risk can be greater if there is a family history of a specific genetic disorder.

Disputed Paternity

Difficulty in genetic counseling may arise if the socially accepted father is not the real biologic father.

PROBLEMS WITH CHROMOSOMAL PRENATAL DIAGNOSIS

Mosaicism

Its likely consequences and severity is often difficult to interpret, especially in CVS samples, where mosaicism is often confined to the placenta.

Culture Failure

Unexpected or Unrelated Adverse Findings

Occasionally, prenatal chromosomal analysis performed to rule out aneuploidy may reveal a common variant, a rare rearrangement, or a marker chromosome. As its significance in fetus is not known, parental chromosomal analysis should be done to rule out a de novo or inherited abnormality. Unbalanced or de novo structural rearrangements may cause serious fetal abnormalities.

POINTS TO REMEMBER

1. Hereditary diseases may manifest at the time of birth or several years later in life.
2. All congenital defects observed at the time of birth are not necessarily inherited. Some of these may be due to teratogenic effect of drugs, infections or irradiation during the first trimester of pregnancy.
3. A degree of clinical variability exists in the presentation of certain genetic disorders. This variable expression of the mutant gene is attributed to the degree of penetration of the gene. Thus one member of the family may show all the features of a genetic disease, while his or her siblings may show only mild forms of the disorders with one or the other sign.
4. Genetic counselor should interpret the anticipated risk of recurrence of the inherited disorder in the future siblings in a meaningful manner so that the family can arrive at a rational decision. The counselor has a particularly important responsibility in reassuring the parents that the risk of recurrence is low in case of disorders with multifactorial inheritance. In sporadic mutations and most of chromosomal disorders, there is only a small or no risk of recurrence.
5. While conveying information to the parents the physician should be extremely cautious. He should take special care not to infuse a sense of guilt in the parents. In case of X-linked disorders, it will be desirable to temper the blame on the mother, lest she is castigated by her husband or in-laws (Indian scenario).

CONCLUSION

Genetic counseling has an integral role in the management of genetic disorders. Counseling should be nondirective,
psychoeducational and involve good communication along with the latest information, confidentiality and truthfulness. Pediatricians and Gynecologists are the primary physicians for the diagnosis, and management of children and high-risk couples with genetic disorders. Also besides treating the patients, physicians should make the parents or couple aware of the genetic disorder, risk of recurrence, prognosis and PND. PND of any malformation is not the end of the diagnosis. It is an unexpected dilemma. It poses a great stress on the family, long-term guilt and need for support. Decision regarding termination or continuation is difficult. So accurate prognosis has to be defined keeping in mind that each pregnancy is precious and there is always a desire for continuation in couples. Establishment of clinical standards and use of professional organizations to act as a resource for clinicians, the public and legislatures is needed. Due to the increased requirement for genetic counseling, an expansion of genetics training for residents, clinicians and the development of computer-based interactive video programs for genetic counseling is recommended.

SECTION 2

Medical Disorders in Pregnancy
Anemia in Pregnancy

INTRODUCTION

Anemia is a global problem. Its prevalence in India is about 60% and may increase to 80% during pregnancy. It directly or indirectly contributes to a significant proportion (about 40%) of maternal deaths. During pregnancy there is a dramatic increase in plasma volume (50%) and cell mass (18–25%). These differential changes cause a dilution decrease in hemoglobin concentration, known as “physiological anemia in pregnancy”. This physiological anemia often gets corrected following iron therapy so its existence is now questioned. This is maximal at 32 weeks of gestation. Poverty, ignorance, malnutrition, food taboos, repeated pregnancy in a limited period of time, parasitic and helminthic infestation and malaria contribute significantly and hemoglobinopathies in a small proportion, to the causation of anemia in our country. Over 90% of anemia is due to red cell iron deficiency associated with depleted iron stores and deficient intake. Infections inhibit incorporation of iron from stores into hemoglobin. Folate deficiency is a minor cause and vitamin B12 deficiency hardly ever causes anemia in pregnancy.

In the Indian context, the word “MA” means “malnourishment and anemia”. Anemia is the most common medical disorder in pregnancy globally. Its prevalence, etiology and severity differ in different populations, being more common in the nonindustrialized countries (56%) where it is responsible for very high maternal (40–60%) and perinatal mortality rates. In industrialized countries, nearly 18% of women are anemic during pregnancy. In India, this figure is as high as 88%. Girls in our country are deprived of good diet in their childhood, and therefore, enter adulthood with malnutrition, anemia and low iron stores. Anemia antedates pregnancy, is aggravated by increased requirements during pregnancy, blood loss at delivery, and infections in the antenatal and postnatal periods. Rapid succession of pregnancies all the more worsens it.

DEFINITION AND SEVERITY OF ANEMIA IN PREGNANCY

The World Health Organization defines anemia in pregnancy as hemoglobin (Hb) concentration of less than 11 g/dL and a hematocrit of less than 0.33. The cut off point suggested by the Centers for Disease Control (CDC) USA is 10.5 g/dL in the second trimester.

The Indian Council of Medical Research (ICMR) categorizes anemia as mild (10–10.9 g/dL), moderate (7.0–10.0 g/dL), severe (< 7.0 g/dL) and very severe (< 4.0 g/dL). The relative prevalence of mild, moderate, and severe anemia are 13%, 57% and 12% respectively in India (ICMR unpublished data).

CLASSIFICATION

- Physiological anemia of pregnancy
- Pathological:
  I. Deficiency anemias (isolated or combined)
    - Iron deficiency
    - Folic acid deficiency
    - Vitamin B12 deficiency
    - Protein deficiency
  II. Hemorrhagic
    - Acute: Abortions, ectopic pregnancy, hydatidiform mole, antepartum hemorrhage (APH), postpartum hemorrhage (PPH)
    - Chronic: Hookworm infestations, bleeding piles
  III. Hereditary
    - Thalassemias
    - Sickle cell disorders
    - Other hemoglobinopathies
  IV. Hemolytic
    - Extrinsic causes: Acquired immune hemolytic anemia and microangiopathic hemolytic anemia
Medical Disorders in Pregnancy

- **Intrinsic causes** (hereditary): Red blood cell (RBC) membrane defects and RBC metabolism defects
- **V. Bone marrow insufficiency**: Hypoplasia or aplasia due to radiation, drugs (aspirin, indomethacin)
- VI. Anemia of infection (malaria, tuberculosis)
- VII. Chronic disease (renal) or neoplasm.

**PHYSIOLOGICAL ANEMIA OF PREGNANCY**

- There is disproportionate increase in plasma volume, RBC volume and Hb mass during pregnancy leading to hemodilution.
- There is increased demand of iron especially in the second half of pregnancy, which even an adequate diet cannot provide, causing physiological iron deficiency during pregnancy.
- There is fall in Hb, hematocrit value, serum iron levels, an increased iron binding capacity and increased rate of iron absorption in second half of pregnancy.
- Thus, the fall in Hb concentration during pregnancy is both due to hemodilution and negative iron balance.
- The physiological anemia is normocytic and normochromic in type, with Hb 10 g%, RBC 3.2 million/mm³, packed cell volume (PCV) 30% and normal morphology of RBCs with central pallor.
- For proper erythropoiesis iron, folic acid, Vitamin B₁₂, Vitamin C, Vitamin B₆, Vitamin A, riboflavin, erythropoietin, zinc, copper, cobalt, androgens and thyroxine are required in adequate amounts.
- Increased requirements, deficient supply or inadequate reserve of any of these constituents interfere with normal erythropoiesis and thereby anemia.

**EFFECTS OF ANEMIA ON PREGNANCY**

- **Maternal**
  - Mild anemia may not have any adverse effect on pregnancy and labor
  - Moderate anemia causes weakness, fatigue and poor work performance
  - **Causes of severe anemia:**
    - During pregnancy - Preeclampsia (31.2%), Abruptio placentae, Preterm labor (28.2%), Cardiac failure (especially at 30–32 weeks)
    - Infections
    - During labor - Uterine inertia, Postpartum hemorrhage, Cardiac failure, Shock
    - During puerperium - Sepsis, Subinvolution

- **Fetal** - Failing lactation
- - Venous thrombosis
- - Pulmonary embolism
- - Preterm birth
- - Small for gestational age baby/ intrauterine growth retardation (SGA/IUGR)
- - Birth anoxia/Low Apgar score
- - Intrauterine death/still birth
- - Low mean weight
- - Infection
- - Cognitive and affective dysfunctions
- - Iron deficiency anemia
- - Hypertension (in later life).

**EFFECTS OF PREGNANCY ON ANEMIA**

- Pregnancy aggravates any pre-existing anemia
- Severely anemic patients become symptomatic by the end of second trimester.

**RISK PERIODS FOR MATERNAL MORTALITY**

- 30–32 weeks of pregnancy
- During labor
- Immediately following delivery
- Puerperium (pulmonary embolism, cardiac failure).

**IRON DEFICIENCY ANEMIA**

Iron deficiency anemia has been defined as microcytic hypochromic anemia, when body iron store becomes inadequate for the need of normal erythropoiesis. Body iron store must be exhausted before red cell production is reduced; therefore, anemia occurs at a late stage of iron deficiency. Iron store depletion occurs as a result of an imbalance between normal physiological demands such as body growth, menstrual blood loss and pregnancy, and the level of dietary iron intake, the efficiency of iron absorption and utilization (Fig. 1).

- Iron deficiency anemia (IDA) is the most common type of anemia in pregnancy
- Total iron requirements vary with the body weight of the mother and the size and maturity of the fetus
- On an average approximately 1000 mg of iron is required during pregnancy. This is distributed in fetus, placenta, expanded red cell mass, blood loss at delivery and obligatory losses through normal routes
- Iron is also conserved by amenorrhea during pregnancy. After deducting this conserved iron, an additional 500–600 mg of iron is required in pregnancy (i.e. 4–6 mg/day of absorbed iron)
The average daily diet contains 10–20 mg of iron. As iron absorption is only 10%, for 4–6 mg/day absorption, at least 40–60 mg elemental iron should be available in the diet. Iron loss is fairly constant. Thus, the iron balance is mainly dependent on the regulation of iron absorption. Iron levels are maintained in short-term by increased absorption in deficiency states and by the amount of bioavailable iron present in the food, in the long-term. Iron is absorbed in the ferrous form from the duodenum and jejunum and is transported in the blood in combination with transferrin (α-glycoprotein). Iron is transported into the cells through attachment of transferrin to specific membrane-bound receptors. Iron is stored in reticuloendothelial cells in liver, spleen, bone marrow, hepatocytes and myocytes. Dietary iron is present in two forms, i.e. heme and nonheme iron. Heme iron is better absorbed (upto 35%) than nonheme iron (5%), but the heme iron is the smaller fraction of the dietary iron. Nonheme iron is mostly in ferric form; needs to be reduced to ferrous form for absorption. Sources of heme iron are animal blood, flesh and viscera. Sources of nonheme iron are cereals, seeds, vegetables, milk and eggs. Absorption of heme iron is not affected by any other foods simultaneously ingested but that of nonheme iron is affected by several factors (Table 1). Heme iron itself facilitates absorption of nonheme iron in a mixed diet.

**Dietary Sources of Iron**

### Rich Sources
Liver, meat, poultry, fish, eggs, yolk, dry fruits, beans, green leafy vegetables, legumes, nuts, jaggery, apple, banana, etc. are rich sources of iron.

### Poor Sources

**Milk and milk products:**
- Although iron absorption is increased during pregnancy, the absorbed iron and the iron mobilized iron stores are usually inadequate to meet the demands. Iron supplementation, therefore, becomes necessary during pregnancy especially in the nonindustrialized countries.
- The fetus obtains iron from maternal transferrin regardless of maternal iron stores. The placenta traps maternal transferrin, removes the iron, and actively transports it to the fetus, mainly in the last 4 weeks of pregnancy.

Iron deficiency anemia is very much prevalent in the tropics, among women of childbearing age, especially in the low socioeconomic group.

**CAUSES**

- Dietary habits
  - Consumption of low bioavailability diet
  - High phosphate and phytic acid in diet forming insoluble iron compounds
  - Food faddism (due to customs and rituals, pregnant women are not allowed to eat many food items)
  - Pica (ingestion of substances having no dietary value)
  - Loss of appetite
  - Hyperemesis gravidarum
- Faulty iron absorption
  - Worm infestation
  - Amebiasis
  - Giardiasis
  - Hypochlorhydria
- Increased iron loss
  - Menorrhagia
  - Repeated pregnancies
  - Bleeding piles
  - Prolonged lactation
  - Hookworm infestations
  - Excessive sweating
  - Schistosomiasis
  - Chronic malaria
  - Dysentery
- Nonpractice of active management of third stage of labor (domiciliary confinements)
- Infections—(interfere with erythropoiesis, e.g. asymptomatic bacteriuria)
- Prepregnancy poor iron reserve
- Teenage pregnancy.

**CLINICAL FEATURES**

The clinical features depend on the degree of anemia.

**Symptoms**

- Mild and moderate anemia may be either asymptomatic or cause weakness, fatigue, lassitude, indigestion and loss of appetite
- In severe anemia, additionally there may be palpitation, breathlessness, giddiness, edema and general anasarca
- If bleeding is the cause of anemia, the patient will complain of it, e.g. bleeding piles.

**Signs**

- Pallor of varying degree, glossitis, stomatitis, and edema due to hypoproteinemia and preeclampsia
- Soft systolic murmur in mitral area (hyperdynamic circulation)
- Fine crepitations at the bases of lungs (congestion).

**MANAGEMENT**

- Diagnosis
- Treatment
  - Preventive
  - Curative
  *The treatment must be preceded by an accurate diagnosis of the cause and the type of anemia.*

**DIAGNOSIS**

- Detailed history
- Clinical examination
- Hemoglobin estimation (simple, cost effective and practical method)
- Hematocrit is reduced, < 33% (Normal 36–46%)
- Peripheral blood smear
  - Differentiates IDA from megaloblastic and hemolytic anemias
  - In IDA, there is microcytosis, anisocytosis, poikilocytosis, hypochromasia and target cells in blood smear
- RBC count—decreased (Normal 4.0–5.20 million/mm³)
- MCV (mean corpuscular volume)—decreased (Normal 78–100 fl)
- MCH (mean corpuscular Hb)—decreased (Normal 26–34 pg/cell)
- MCHC (mean corpuscular Hb concentration)—decreased (normal 31–37 g/dL)
- Reticulocyte count—increased (Normal 0.5–2.5% red cells).

**Red Cell Distribution Width (RDW) (Fig. 2)**

- An index of anisocytosis
- Increase in IIDA and normal in thalassemia (Table 2).

**Serum Ferritin Level (a High Molecular Weight Glycoprotein Circulating in Plasma)**

- Indicates iron stores
- Decreased in IIDA < 12 mg/L (normal 15–300 mg/L)
- First test to become abnormal in IIDA.

**Transferrin Saturation**

- Indicates iron supply to the tissues
- Decreased in IIDA < 15% (Normal 20–45%)
- Second test to become abnormal in IIDA.

**Serum Iron Levels**

- Decreased in IIDA < 60 mg/dL (normal 60–120 mg/dL)
CHAPTER 7

Anemia in Pregnancy

Total Iron Binding Capacity

- Increased in IDA > 350 mg/dL (normal 300–400 mg/dL).

Free Erythrocyte Protoporphyrin (FEP)

- Indicates iron supply to the developing RBCs
- Increased in IDA; and normal in thalassemia (normal < 35).

Serum Transferrin Receptor (TfR)

- Reflects tissue iron status
- Increased in IDA
  - Very good marker of IDA in pregnancy, (test not available routinely).

Bone Marrow Examination

- Stainable iron seen in erythroblasts as blue granules by potassium ferrocyanate
- Accurate method of knowing iron stores
- Invasive and impractical test (not done routinely).

Indications of Bone Marrow Aspiration

- No response to iron therapy after 4 weeks
- Suspected aplastic anemia
- Kala-azar
  - Stool examination for ova and cysts (for 3 consecutive days) in all cases.

Urine Routine and Microscopic Examination

- For proteins, sugar, pus cells, occult blood and schistosomes (in high prevalence areas)
- Urine culture and sensitivity (for bacteriuria)
- Peripheral blood smear for malarial parasite in all cases
- Renal function tests (in suspected renal disease)
- Serum proteins (in hypoproteinemia).

Abbreviation: TIBC, total iron binding capacity.

TREATMENT

Prevention

Prophylaxis in Nonpregnant Women

- Prevention of iron deficiency should start before pregnancy
- The amount of 60 mg of iron along with folic acid (100–200 μg) every day for three months in the prepregnancy stage.

Iron Supplementation During Pregnancy (Flow chart 1)

- The World Health Organization (WHO) recommends universal oral iron supplementation, 60 mg elemental iron and 250 μg of folic acid once or twice daily for 6 months in pregnancy, in countries with a prevalence of anemia < 40% and for an additional 3 months postpartum in countries where the prevalence is > 40%.
- Ministry of Health, Government of India recommends intake of 100 mg of elemental iron with 500 μg of folic acid daily in the second half of pregnancy for a period of 100 days
If the compliance is poor, weekly or twice weekly oral iron supplements may be given.

Two injections of iron dextran (250 mg each) given intramuscularly at 4-week intervals also give good results.

**Treatment of Worm Infestation**
- Albendazole (400 mg) single tablet or
- Mebendazole (100 mg) twice daily for 3 days, given to all anemic pregnant women in the second and third trimesters.
- Change in defecation habits
- Avoidance of walking bare-footed.

**Improvement of Dietary Habits**
- Pregnant women should eat high iron bioavailable diet, which is within their reach
- Cooking of food in iron utensils
- Avoidance of tea, coffee and overcooking of food
- Adding lemon juice to the food
- Consumption of iron-rich natural mineral water.

**Improvement of Sanitation and Personal Hygiene**

**Improvement of Female Literacy Status**

**Food Fortification with Iron (e.g. of Salt)**

**Reproductive Interventions**
- Prevention of teenage pregnancies
- Reducing total number of pregnancies
- Spacing the pregnancies.

**Curative Treatment**

**General Measures**
- Diet rich in iron, protein and vitamins is prescribed
- Treatment of the cause of anemia.

**Specific Therapy**

**Principles:**
- To raise the Hb as near as normal
- To replenish iron stores.

**Choice of Therapy (Depends Upon)**
- Severity of anemia
- Duration of pregnancy
- Associated complications.

**IRON THERAPY**

Ideally all anemic patients should be admitted but due to shortage of bed only severe anemic patients are usually admitted. The management of iron deficiency in pregnancy will be governed by the etiology of the deficiency state and severity of anemia. Iron therapy can be divided into:
- Oral iron therapy
- Parenteral iron therapy.

**Oral Iron Therapy**
- If the woman presents in mid trimester or early third trimester oral iron therapy is started
- Available preparations are ferrous sulfate, ferrous gluconate, ferrous fumarate and ferrous succinate
- Ferrous sulfate (200 mg tablet containing 60 mg elemental iron) is given thrice daily till the blood parameters become...
normal. Maintenance dose—one tablet daily is given for 3 months postpartum

- If the compliance is poor (gastrointestinal side effects)
  - Reduce the dose
  - Give tablet with meals or
  - Give the drug less frequently

- Indications of response to therapy
  - Feeling of well-being
  - Improved looks and appetite
  - Rise in reticulocyte count (within 5–10 days), Hb 1.0 g/dL/week) and hematocrit.

If there is no significant clinical or hematological improvement within 3 weeks, diagnostic re-evaluation should be done. The ability of the patient to tolerate oral preparations will also be a factor. Using iron rich spa water as a prophylaxis against iron deficiency in pregnancy has a good place, because it is well tolerated and provides iron in a highly bioavailable form.

Iron (III) Polymaltose Complex

The iron (III) polymaltose complex dextriferron is one of the few available oral iron (III) compounds and belongs to the class of so-called slow-release iron preparations. Polymaltose acts like a casing around the trivalent iron, ensuring slower release of the iron from the complex. The advantages of this iron preparation are, firstly, its favorable side-effect profile compared to iron (II) salts as a result of the slow release, and, secondly, that it can be taken with meals. Various authors have postulated that iron polymaltose complexes have lower toxicity compared with iron sulfate salts, due to reduced formation of oxygen radicals and thus decreased plasma lipid peroxidation. In studies carried out to date, their bioavailability is comparable to that of iron (II) sulfates and fumarates.

Dosage of the iron (III) polymaltose complex (Maltofer®)
(Fe III= 50 mg);
- Drops: 40–120 drops/day
- Tablets: 200–400 mg/day
This is true either during or after meals—in contrast to iron (II) compounds.

Iron Compounds in Combined Preparations

Additives such as succinic acid, fumaric acid, gluconic acid, glutamic acid, aspartic acid and lactic acid, certain vitamins and trace elements (Cu, Co, Mn) form chelates with iron and thus keep divalent iron available for absorption. Ascorbic acid is a useful adjunct for the stabilization of Fe (II) ions against oxidation. Combining iron (II) salts with ascorbic acid increases the absorption of iron. According to the literature, this can lead to an increased side-effect rate due to the more rapid release of iron. In addition, the combination with ascorbic acid can lead to increased formation of toxic hydroxyl radicals.

Oral iron salts are available in a huge variety of combined preparations; their inclusion in multivitamin and trace element preparations, in particular, offers no advantages over the administration of iron alone. The presence of magnesium, calcium and zinc in combined products can inhibit the absorption of iron. Combining different iron (II) salts in one preparation also offers no advantages. Tetracyclines, antacids such as omeprazole and bile acid sequestrants such as cholestyramine can impair iron absorption. Conversely, the bioavailability of some agents, such as gyrase inhibitors, L-thyroxine and penicillamine, can be reduced by the concomitant oral administration of iron.

Causes of Failure of Response to Oral Iron Therapy

- Noniron deficiency microcytic anemia (e.g. thalassemia, pyridoxine deficiency, lead poisoning)
- Noncompliance
- Faulty iron absorption (gastrointestinal disorders)
- Persistent blood loss (hookworm infestation, bleeding piles)
- Infection that suppresses erythropoiesis
- Concomitant folate deficiency.

Reasons for Failure of Oral Iron Therapy

- Additional complicating disorders
- Drugs that inhibit erythropoiesis (e.g. cytotoxic agents, immunosuppressants).

Parenteral Iron Therapy

Parenteral iron can be used in patients receiving recombinant erythropoietin to guarantee adequate iron delivery. Parenteral iron is available as ferric hydroxide dextran complex (50 mg/mL), ferric gluconate and iron sucrose. Iron can be given by intramuscular injection in small amounts. These injections are painful and can cause skin staining. To prevent skin staining, a “Z”-shaped injection track should be followed. Intermittent intramuscular injection of 1000 mg in 4 divided doses can be given prophylactically during pregnancy to prevent anemia. For the treatment of iron deficiency anemia; the preferred method of parenteral iron administration is total dose infusion by slow intravenous infusion with 0.9% sodium chloride with all precautions to prevent anaphylactic reaction. The amount of iron needed can be calculated as follows: Body weight (kg) × 2.3 × (15-patient’s hemoglobin g/dL) + 500 mg to 10000 mg (for store) = Total dose (mg).
- It has no advantage over oral therapy if oral iron is well tolerated and absorbed
- The rise in Hb concentration is same as with oral iron (i.e. 1 g/dL/week)
- It is expensive and could be “hazardous”
- Advantage of parenteral therapy is certainty of its administration
• Oral iron is to be stopped 24 hours prior to parenteral therapy to avoid toxic reaction.

**Indications**

Indications for administering parenteral iron therapy are tabulated in Table 3.

<table>

</tbody>
</table>

**Preparations for Parenteral Iron Therapy**

1. **Type I complexes (Iron dextrin, iron dextran):** These iron complexes have high molecular weight (> 100000 Dalton) and high stability (e.g. Imferon®). The plasma half-life of the type I complexes is 3–4 days. The dextran component, in particular, can lead to severe allergic reactions. This reaction appears to be less pronounced with the dextrans.

2. **Type II complexes (Iron hydroxide-sucrose complex):** These are complexes of so-called medium stability, with a molecular weight of 30000–100000 Dalton (Venofer®). Maximum plasma concentrations are reached as early as 10 minutes following bolus administration (30 mg/L). The plasma levels return to pretreatment values 24 hours after administration. The half-life is 5.5 hours, and positron emission tomography (PET) studies show immediate accumulation in the bone marrow, occurring in parallel with the fall in plasma levels. In patients, 70–97% of the iron is used for erythropoiesis, depending on the severity of their iron-deficiency anemia. General side effects include: metallic taste, feeling hot, nausea, local irritation and dizziness.

3. **Ferric carboxymaltose (Ferinject®):** Ferric carboxymaltose is a nondextran containing intravenous (IV) iron agent designed to be administered in large doses by rapid (15 minutes) IV infusions. The ability to safely infuse a single dose as large as 1000 mg reduces the need for repeated IV infusions and renders this agent a potentially ideal candidate for various indications in anemia therapy.

4. **Type III complexes (Iron gluconate, iron ammonium citrate, iron hydroxyxide sorbitol complex):** Iron gluconates (e.g. Ferlicit®). They are unstable, labile complexes with molecular weights of less than 50000 Dalton. Low stability compared to iron dextrans and iron sucroses complexes, type III complexes show less binding to transport proteins, with greater quantities of free iron being released in the short term. Maximum transferrin saturation following the administration of iron gluconate has been described in various studies.

Free iron is deposited in the parenchyma of various organs. Free radicals lead to lipid peroxidation and, compared with type I/II complexes, to greater tissue toxicity. The iron gluconates, in particular, are comparable to the iron sucroses with regard to allergic or anaphylactic reactions, and, thus, like the iron sucroses, have a better side effect profile than the iron dextrans.

**Iron Sucrose Complex**

Iron sucrose is effective in pregnant and postpartum patients who do not respond to oral iron, who are noncompliant to oral iron, or who treated with rhHuEPO. In both cases, according to the present data, the expected hemoglobin increase and time for therapy are predictable in responding patients. Whether it is reasonable to wait for a response to oral iron in moderate to severe anemia is therefore questionable. Indications for the use of iron sucrose complex are: preexisting (moderate-severe) anemia; no effect of oral iron; side effects of oral iron; refusal of blood transfusion; limited time until delivery; coexisting risks (e.g. bowel disease, renal diseases); pre- and postoperative period and postpartum anemia.

In accordance with obstetrics clinic guidelines, an incremental treatment plan is used in anemia management. Prerequisites for the use of parenteral iron include diagnostic investigations and fulfillment of the following inclusion criteria:

- Hemoglobin (Hb) < 10 g/dL
- No effect of oral iron therapy (160–200 mg/d) over 2 weeks (i.e. no Hb increase and/or reticulocyte response)
- Proven iron deficiency (serum ferritin < 15 µg/L)
- Exclusion of hemoglobinopathy or other red cell disorders
- Exclusion of acute inflammatory state (C-reactive protein determination)
- Gestational age 16 weeks.

**Practical use of iron sucrose at the Zurich clinic of obstetrics:** The substance is administered through a venous butterfly cannula, once correct positioning in the vein has been tested with NaCl. Iron sucrose can be administered undiluted as a bolus or diluted, e.g. to 100–200 mL of isotonic NaCl solution as a short infusion. Administration of a test dose (1 mL) is required in different countries. The bolus injection may be given over 5–10 minutes; however, a short infusion over approximately 20 minutes is considered safer. The maximum single dose is 200 mg. We generally give two doses a week to achieve a target Hb value of 11 g/dL. The treatment can be given on OPD basis.

**Dosage Calculation**

Elemental iron needed (mg) = Iron deficit (Normal Hb – Patients Hb) × weight (kg) × 2.21 +1000
Anemia in Pregnancy

Parenteral preparations:
i. Iron dextran (Imferon®) IM/IV
   - Complex of ferric hydroxide
   - Colloidal solution containing 50 mg/mL elemental iron
   - 2 mL ampoule (single dose)
   - 10 mL vial (multidose)

Intravenous (IV) Infusion
- Total dose of iron required, is administered by a single IV infusion
- To be given by a doctor in a hospital setting
- Initially a small test dose (0.5 mL) is given and the patient is observed for 1 hour for any adverse reaction
- Measures to manage reaction are to be kept ready (e.g. inj epinephrine, inj hydrocortisone and oxygen).
- If the test dose is tolerated, iron dextran diluted in normal saline or 5% dextrose is given slowly over several hours
- Monitor to see for any adverse reaction (e.g. chest pain, chills, rigors, hypotension, breathlessness, hemolysis and anaphylaxis)
- Stop infusion and manage reaction in the event of such need.

Intramuscular (IM) Route
- More popular
- Lesser side effects.
Dose: Initial test dose (few drops) of iron dextran or iron sorbitol citrate, is given IM, when tolerated, is followed by 2 mL (100 mg) daily or on alternate days, deep IM in gluteal region, using Z technique.

Side Effects
Local
- Pain at injection site
- Skin discoloration
- Abscess formation.

Systemic
- Nausea, vomiting
- Headache
- Fever
- Arthralgia
- Lymphadenopathy
- Flushing
- Palpitation
- Anaphylactic reaction.

Indications of Blood Transfusion
If there is not enough time to achieve a reasonable hemoglobin for delivery, acute blood loss, anemia refractory to iron therapy, associated infection, or severe anemia beyond 36 weeks, then blood transfusion with all its hazards should be considered. Packed red cell transfusion is given with meticulous care to prevent severe circulatory overload and pulmonary edema. Blood transfusion corrects anemia, but more important is that it increases oxygen carrying capacity and stimulates erythropoiesis. Exchange transfusion may be indicated in cases of cardiac failure due to severe anemia, cases of marked anemia requiring surgery or as a safer alternative to blood transfusion. It raises the hemoglobin concentration very effectively in severely anemic women without inducing circulatory overload.
- Severe anemia near term
- Antepartum or postpartum hemorrhage
- Refractory anemia
  - Packed cells are preferred
  - Improvement is expected after 72 hours.

Drawbacks of Blood Transfusion
- Transfusion reaction
- Cardiac failure
- Pulmonary edema
- Preterm labor.

Stimulation of Erythropoiesis with Recombinant Erythropoietin (rhEPO)
The growth factor recombinant human erythropoietin (rhEPO), a glycoprotein (molecular weight: 30,400 Dalton) is identical to endogenous erythropoietin and acts as a selective growth and survival factor for erythroid cells. The combination of rhEPO and parenteral iron is superior to iron treatment alone and can be considered as a good option when treating severe anemia or if the patient refuses donor blood. The effect of rhEPO is dose dependent; single intravenous injection of 150–300 IU/kg are sufficient.

Antenatal Care
- More frequent antenatal check-ups required
- Fetal monitoring for growth and well-being
- Detection and management of complications (Cardiac failure, preterm labor)
- Hospitalization of severely anemic patients.

MANAGEMENT DURING LABOR
First Stage
- Blood cross-matching on admission
- Comfortable position in bed
- Adequate pain relief
- Oxygen inhalation (SOS)
- Digitalization (SOS)
• Antibiotic prophylaxis
• Strict asepsis
• For preterm labor β mimetics and steroids given cautiously (to avoid pulmonary edema).

Second Stage
Prophylactic forceps application.

Third Stage
• Active management (except in very severely anemic patients)
• Postpartum hemorrhage to be managed energetically (these patients tolerate bleeding poorly).³

Puerperium
• Adequate rest
• Iron and folate therapy to continue for 3 months
• Careful watch for failing lactation, subinvolution, thromboembolism and infection.

Contraception
• Sterilization (if family is complete)
• Oral contraceptive pills
• Barrier methods.

MEGALOBLASTIC ANEMIA IN PREGNANCY
In megaloblastic anemia, deoxyribonucleic acid (DNA) synthesis is affected. There is derangement of red cell maturation with production of abnormal precursors (megaloblasts) (Fig. 3) in the bone marrow, which are released into the circulation as macrocytes. Megaloblastic anemia is due to folic acid or vitamin B₁₂ deficiency.³

Folic acid at a cellular level is reduced to dihydrofolate acid and then to tetrahydrofolate acid (folic acid) which is essential for the cell growth and division
• Folic acid requirements are increased during pregnancy for the growth of the fetus, placenta, maternal red cell mass and myometrium³⁹
• Plasma folate levels decrease as pregnancy advances, reaching nearly half of nonpregnant values at term.
• Folate deficiency complicates nearly one-third of all pregnancies in nonindustrialized countries.
• Rich sources are green leafy vegetables (broccoli, spinach), Brussels sprouts, beans, yeast, liver, kidney, fruits, cereals, and nuts (almonds, peanuts).
• Poor source—goat’s milk
• It is heat labile, rapidly destroyed by boiling or steaming
• Absorbed from duodenum and upper jejunum
• Stored in the liver; body reserves of folate are low (10 mg)
• Daily requirements:
  – Nonpregnant women: 50–100 µg/day
  – Pregnant women: 300 µg/day
  – Lactating women: 150 µg/day.

Causes
• Reduced dietary intake (poverty)
• Prolonged cooking of food
• Nausea, vomiting, anorexia
• Malabsorption syndrome/gastrointestinal diseases
• Increased plasma clearance of folate by the kidneys
• Transfer of folate from mother to the fetus
• Uterine hypertrophy
• Expanded red cell mass
• Liver disorders
• Chronic alcoholism
• Antifolate medication—antiepileptic drugs (e.g. phenytoin, primidone), pyrimethamine and trimethoprim

FOLIC ACID (FOLATE) DEFICIENCY ANEMIA³⁹
• Folic acid along with iron is one of the important nutrients during pregnancy

Fig. 3: Megaloblastic anemia. Peripheral blood smear showing neutrophil with segmented nucleus
Anemia in Pregnancy

- Low body reserves
- Vitamin C deficiency
- Increased demand—multiple pregnancy, repeated child-births, hookworm infestations, bleeding piles, hemolytic anemias, hemoglobinopathies, chronic malaria, other infections
- Folate requirements are increased by iron therapy due to hyperplastic bone marrow. Therefore, folate is always given with iron for better results.

Clinical Features
- Asymptomatic patient
- Pallor
- Nausea, vomiting, diarrhea
- Loss of appetite
- Unexplained fever
- Glossitis
- Bleeding spots in skin, conjunctiva
- Hepatosplenomegaly.

Effects on Pregnancy

Maternal
- Abortion
- Preterm labor
- Abruptio placentae
- Preeclampsia.

Fetal
- Intrauterine growth retardation (IUGR)
- Preterm births
- Neural tube defects (NTDs)

- Cleft lip and cleft palate
- Megaloblastic anemia in the neonate.

MANAGEMENT

Diagnosis
- Hb < 10 g/dL
- MCV > 100 fl
- MCH > 33 pg/cell
- MCHC: Normal (31–37 g/dL)
- Peripheral smear:
  - Macrocytosis, anisocytosis
  - Hypersegmentation of neutrophils
  - Giant cell polymorphs
  - Megaloblasts
  - Neutropenia
  - Thrombocytopenia
  - RBCs show basophilic stippling, Howell-Jolly bodies and Cabot ring
- Low serum folate (< 3 ng/dL)
- Low RBC folate (< 150 ng/dL)—more useful test
- Normal or high serum iron levels
- High urinary formiminoglutamic acid (FIGLU) following a loading dose of histidine (obsolete test)
- High serum lactate dehydrogenase (LDH) and homocysteine levels
- Low reticulocyte count
- Bone marrow aspiration—megaloblastic picture (rarely done).

Prophylaxis
- Increased dietary intake
- Folic acid supplementation (recommendations).
WHO: 400 µg/day along with 60 mg elemental iron in antenatal and 3 months postnatal period.

Ministry of Health, Government of India: 500 µg/day with 100 mg elemental iron in antenatal and 3 months postnatal period.

- For prevention of NTD, 400 µg/day in low-risk cases and 5 mg/day in high-risk cases in the periconceptional period
- Food fortification with folic acid

**Treatment**

- Established folate deficiency in pregnancy is treated with 5 mg/day folic acid along with iron orally, to be continued in the postnatal period for 3 months
- Lactation provides an added folate stress, 25 µg/day is secreted in the breast milk
- In undiagnosed vitamin B₁₂ deficiency, however, folate therapy worsens neuropathy so add vitamin B₁₂ with folate therapy.
- Add vitamin C (100 mg thrice daily)—converts folic acid to folinic acid.

**Indicators of Response to Therapy**

- Fall in serum LDH levels (within 3–4 days)
- Rise in reticulocyte count (within 5–8 days)
- Parenteral folate is indicated in: (i) gastric intolerance and (ii) advanced pregnancy
- Blood transfusion is required in severely anemic patients (rare).

**Labor and Delivery**

No specific recommendations of management are there if the patient is hemodynamically stable.

### VITAMIN B₁₂ DEFICIENCY ANEMIA

Vitamin B₁₂ (cobalamin) cannot be synthesized in the human body and only dietary source of cobalamin is animal products, meat and dairy products. Pregnancy does not alter its absorption and does not have vast impact on maternal store. The dietary intake of cobalamin is more than adequate for the body’s requirements; except in the vegetarian and breast fed infants of mothers with significant vitamin B₁₂ deficiency. Deficiency of vitamin B₁₂ is almost due to malabsorption. Addisonian pernicious anemia is due to cessation of secretion of intrinsic factor from gastric mucosa which is very unusual during reproductive years. Vitamin B₁₂ deficiency is associated with infertility and pregnancy is likely only if the deficiency is cured.

- This condition is rare
- Serum, RBC and muscle vitamin B₁₂ concentrations decrease during pregnancy
- Vitamin B₁₂ absorption is unaltered in pregnancy
- Tissue uptake is increased under the influence of estrogens
- Smoking decreases serum vitamin B₁₂ levels
- Plasma vitamin B₁₂ binding capacity increases in pregnancy due to increased levels of transcobalamin II
- There is preferential transfer of absorbed vitamin B₁₂ to the fetus
- Pregnancy does not affect maternal vitamin B₁₂ stores
- Minimal amounts of vitamin B₁₂ are required for fetal development. So, not many fetal problems are seen in vitamin B₁₂ deficiency but breast fed infants of mothers with vitamin B₁₂ deficiency show a syndrome characterized by failure to thrive, developmental regression and anemia
- Addisonian pernicious anemia (due to intrinsic factor deficiency) is unusual in reproductive years, rather it causes infertility
- Deficiency is seen in Crohn’s disease, sprue, resection of distal ileum, gastrectomy cases and pure vegetarians
- Rich sources are liver, kidney, meat, fish, eggs, milk and cheese
- Vitamin B₁₂ is not destroyed by cooking
- Stored in the liver
- The average daily diet contains 5–30 µg of vitamin B₁₂
- Daily absorption is 1–5 µg
- Daily requirements (prepregnancy: 3 µg; during pregnancy and lactation: 4 µg).

**MANAGEMENT**

### Diagnosis

- Serum vitamin B₁₂ levels < 90 µg/L
- Elevated methylmalonic acid and homocysteine levels
- Deoxyuridine suppression test can differentiate vitamin B₁₂ and folic acid deficiency.

### Treatment

- Oral Vitamin B₁₂ (10–30 µg/day) along with folic acid is given in patients with dietary deficiency
- In severe deficiency injectable vitamin B₁₂, 1 mg IM on alternate days is given till improvement of neuropathy.

### Dimorphic Anemia

- In tropical countries deficiency of both iron and folic acid are seen together
- Peripheral film may show macrocytic or normocytic, normochromic or hypochromic picture (finding of one type of anemia dominates)
- Bone marrow is megaloblastic.

### Treatment

- Iron and folic acid supplementation in therapeutic dosage
- Intake of green leafy vegetables and fruits
- Avoidance of too much cooking of food.
Hemoglobinopathies

- Hemoglobinopathies are inherited biochemical disorders of Hb with qualitative or quantitative abnormality of globin chain synthesis.
- Subgroups
  - Sickling disorders
  - Thalassemia syndromes.
- Both homozygous and heterozygous forms occur.
- Multidisciplinary team management is required in women during preconception, antenatal, intranatal and postnatal periods.
- Timely screening of women and their partners to identify carriers and those at risk for having an offspring affected with major hemoglobinopathy is essential.

**Sickle Cell Trait (HbAS)**

- Benign condition
- Reproductive performance is unaltered
- Prepregnancy screening and counseling (both partners)
- Offspring having 25% chance of sickle cell disease (SCD), if male partner is a case of SC trait.

**Sickle Cell Disease (HbSS)**

Effects on Pregnancy (Flow charts 2 and 3)

*Maternal (High Maternal Morbidity and Mortality)*

- Sickle cell crisis (painful vaso-occlusive/hemolytic crisis)

**Flow chart 2: Sickling disorders**

- Sickling disorders (Qualitative disorders)*
  - Homozygous Sickle cell disease (SCD) HbSS
  - Heterozygous Sickle cell trait HbAS

*An amino acid substitution in an alpha or beta chain results in synthesis of abnormal Hb.

**Flow chart 3: Etiopathogenesis of sickle cell anemia**

- **HbA**
  - Point mutation
  - 6th Position of &-globin chain
  - Glutamic acid
  - Valine

- **HbS**
  - Oxygenated
  - Deoxygenated
  - HbS solution (RBC)
  - HbS Polymers (RBC) irreversibly sickled

- **Membrane changes increased adhesiveness**

- **Tissues**
  - Microvascular occlusion by sickle cells (infarctions)
  - Painful vaso-occlusive complications
  - Bones
  - Lungs
  - Kidneys
  - Liver
  - Brain
  - Spleen

- **Spleen**
  - Hemolysis
  - Chronic hyperbilirubinemia
  - Jaundice

- **Infection**
- **Acidosis**
- **Dehydration**
- **Hypoxia**
- **Cooling**
SECTION

Medical Disorders in Pregnancy

80

• Acute anemia
• Ischemic injury/organ damage (infarctions, e.g. pulmonary)
• Infections (pulmonary, urinary tract)
• Hypertensive disorders of pregnancy
• Congestive cardiac failure
• Thromboembolism (pulmonary, CVA)
• Postpartum hemorrhage
• Fever, leukocytosis, jaundice.

Fetal (High Perinatal Mortality and Morbidity)

• Abortion
• Preterm birth
• Intrauterine growth retardation.

MANAGEMENT

Diagnosis

• Complete blood count (decreased RBC, increased WBC and platelet counts)
• Blood typing
• Red cell antibody screen
• Low Hb-refractory hypochromic anemia
• Peripheral smear—sickle cells, Howell-Jolly bodies, target cells (Fig. 5)
• Low hematocrit (18–30%)
• Persistent reticulocytosis (10–20%)
• Serum iron levels (high)
• Low serum folate levels
• Hb electrophoresis
• Sickle solubility test
• Liver function tests (increased serum bilirubin)
• Renal function tests
• Serum electrolytes

• Urine culture and sensitivity
• Hepatitis B surface antigen (HBs Ag) test
• HIV test
• Rubella antibody status
• Abdominal ultrasound for gallstones and splenic size.

TREATMENT

Preconception

• Screening (both partners)
• Counseling
  – Counseling against conception until disease status is optimized
  – About the risks of pregnancy
  – About prenatal diagnosis.

Antenatal

• Termination of pregnancy is offered if the fetus is homozygous for SCD (act according to parental wishes)
• Early and frequent antenatal check-ups
• Fetal surveillance and tests for fetal well-being
• Avoidance of air travel
• Antibiotics (when required)
• Folic acid supplementation (5 mg/day)
• Blood transfusion (when required).

Labor and Delivery

• Patient is kept warm
• Good hydration
• Adequate pain relief (epidural analgesia)
• Oxygen inhalation
• Antibiotics
• Continuous cardiotocography (CTG) monitoring
• Avoid prolonged labor (plot partogram)
• Cord blood screening for hemoglobinopathy.

Postnatal

• Good hydration
• Oxygenation
• Monitor for sickle cell crisis
• Early ambulation
• Thromboprophylaxis (when required)
• Contraception
• Neonatal care.

ALPHA THALASSEMA MAJOR
(FLOW CHART 4)

• No alpha chain production
• Fetal hydrops develops (incompatible with life)
• Labor and delivery—problems related to large fetus.
**ALPHA THALASSEMIA MINOR**
- Prepregnancy screening (both partners) and counseling
- Offspring having 25% chance of thalassemia major, if partner is a carrier of alpha thalassemia.
- Definitive diagnosis needs DNA analysis
- Antenatally chorionic villous sampling or amniocentesis done for diagnosis
- Preimplantation blastomere biopsy to select unaffected embryos in IVF cases
- The reproductive performance is not affected
- Folic acid supplementation (5 mg/day)
- Blood transfusion when required.

**BETA THALASSEMIA MAJOR (FLOW CHART 4)**
- Survival beyond teenage years is uncommon.
- If they survive, patients are infertile.

**BETA THALASSEMIA MINOR (FLOW CHART 5)**
- Mild, microcytic, hypochromic anemia (Hb 8–10 μg/dL), not responding to iron therapy
- Diagnosis often missed
- Increased HbA₂ (> 3.5%), normal or increased MCHC and serum iron concentrations (See Table 2)
- Iron overload in tissues
- Increased serum bilirubin (2–3 mg%)
- Reproductive performance unaltered
- Offspring having 25% chance if the partner is also a carrier of beta thalassemia.

**TREATMENT**
- Do not supplement iron
- Folic acid supplementation (5 mg/day)
- Withhold iron chelation therapy in pregnancy

**HEMOLYTIC ANEMIA**

**Causes of Hemolysis**

**Intrinsic**
- Abnormalities of Hb structure and function (e.g. hemoglobinopathies)
- Red cell membrane disorders (e.g. hereditary spherocytosis)
- Red cell metabolism disorders (e.g. pyruvate kinase, G6PD deficiency).

**Extrinsic**
- Red cell directed antibody (acquired immune hemolytic anemia)
- Altered intravascular circulation (microangiopathic hemolytic anemia).

**ACQUIRED IMMUNE HEMOLYTIC ANEMIA (EXTRAVASCULAR HEMOLYSIS)**
- The patient makes antibodies (IgG) against red cell antigens causing hemolysis in reticuloendothelial system.

**Causes**
- Idiopathic
- Diseases
  - Leukemias
  - Lymphomas
  - Viral infections
- Drugs
  - Penicillins
  - Sulfas
  - Quinidine
Collagen vascular diseases [e.g. systemic lupus erythematosus (SLE)].

**Diagnosis**
- Positive direct Coomb’s test
- Raised antinuclear antibody titers (SLE)
- Raised anti-DNA antibody titers (SLE)
- Reticulocytosis (10–30%) (Fig. 6)
- Low Hb
- Splenomegaly.

**Treatment**
- Prepregnancy counseling and optimization of treatment
- Adjustment of steroid therapy (prednisolone 60–100 mg daily)

**Flow chart 5: Pathogenesis of β-thalassemia**

![Flow chart 5: Pathogenesis of β-thalassemia](image)

- Normal
  - Hb
  - HbA–(α2β2)
  - Normal RBC
- Reduced β-globin Synthesis
- β-Thalassemia
  - Abnormal erythroblasts die in bone marrow
  - α-globin aggregates, Microcytic, Hypochromic RBC
  - Ineffective erythropoiesis
- Dietary iron
  - Stomach
  - Increased absorption of iron
  - Heart
  - Liver
  - Secondary hemochromatosis
  - Increased iron deposition
  - Blood transfusions
  - Tissue anoxia
  - Erythropoietin increase
  - Marrow expansion
  - Skeletal deformities
- Anemia
  - Spleen (Hemolysis)
  - Hepatosplenomegaly
  - Increase serum bilirubin

**Fig. 6: Hemolytic anemia (bone marrow smear)**
- Blood transfusion
- Folic acid supplementation (5 mg daily)
- Splenectomy
- Azathioprine (immunosuppression)
- Remission occurs after delivery but the condition can recur in subsequent pregnancies.

**Microangiopathic Hemolytic Anemia (Intravascular Hemolysis) (Flow Chart 6)**

**Causes**
- Preeclampsia/eclampsia (DIVE)
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome (rare)
- Herpetic hepatitis.

**Diagnosis**
- Peripheral smear
  - Fragmented RBCs (Fig. 7)
  - Schistocytes
  - Helmet cells
  - Thrombocytopenia is always present
- Fibrinogen deposition in microvasculature, spontaneous correction after delivery
- Moderate to severe anemia

**Flow Chart 6:** Clinicopathologic effects of hemolysis

![Flow Chart 6: Clinicopathologic effects of hemolysis](image)
• Reticulocytosis
• Low haptoglobin levels
• High serum LDH levels
• Hemoglobinemia and hemoglobinuria.

Treatment
• Treatment of the causes
• Blood transfusion.

APLASTIC ANEMIA
(RARE IN PREGNANCY)

Causes
• Idiopathic
• Infections
• Medications/toxins
• Immunological
• Autosomal recessive inheritance
• Pregnancy itself.

Clinical Features
• Pallor
• Fatigue
• Bruising/hemorrhage
• Infections
• Lymphadenopathy
• Hepatosplenomegaly.

Complications
• High maternal morbidity and mortality rates (30%)
• Intrauterine growth retardation
• Intrauterine fetal death.

MANAGEMENT

Diagnosis
• Pancytopenia
• Bone marrow aspiration/biopsy
  - Marked hypocellularity
  - Hemopoietic tissue replaced by fat
  - Cytogenetic study and chromosomal fragility tests.

Treatment
• Termination of pregnancy (in first trimester)
• Bone marrow transplantation (if no spontaneous recovery after termination)
• Repeated blood transfusions until delivery to maintain hematocrit > 20
• Platelet transfusion (to control hemorrhage)
• Granulocyte transfusions (to combat infections)

CONCLUSION

Anemia in pregnancy is one of the most common medical disorders in India and is responsible for increased maternal morbidity and mortality. In developing countries nutritional anemia is most common but there are also non-nutritional causes of anemia that may be seen in pregnancy, the sickle cell disorders, the thalassemias, hemolytic anemia, etc. which are reviewed in a separate chapter. Prenatal care is the preventive obstetrics. The factors responsible for anemia in pregnancy should be identified and eradicated. Iron supplement to prevent anemia in pregnancy is a well known strategy. The National Nutritional Anemia Prophylaxis Program (NNAPP) advised 60 mg of elemental iron and 500 µg of folic acid daily for 100 days to all pregnant women. Inaccessibility of such program, noncompliance and gastrointestinal malabsorption still remain as major causes of anemia in our country. Malaria and hookworm prophylaxis must be considered in endemic areas. Prevention and management of nutritional anemia is easy and cheap. Along
with the support of the Government, the support of the family, social workers, schoolteachers, media, etc. is necessary. But, do not worry! Conquering anemia is an achievable goal. Educating women will help by increasing awareness of the need for better nutritional status and contraceptive usage, thus limiting and spacing the pregnancies.

So friends, let us join hands so that the word “MA” can mean “MOVEMENT AGAINST ANEMIA”. The Federation of Obstetric and Gynaecological Societies of India (FOGSI) in 2007 initiated a movement of 12 x 12 initiative to achieve hemoglobin levels of 12 g/dL by 12 years.

In 2008, FOGSI has strengthened its drive and commitment toward anemia eradication by giving a call “ERADICATE ANEMIA EVERYDAY”; only you can make a difference.

INTRODUCTION

Pregnancy involves a variety of hematological problems needing shared responsibility from obstetricians, hematologists and neonatologists. The disorders may be harmful or lethal to mother or fetus. Similarly, therapeutic interventions meant to decrease maternal morbidity may harm the fetus. Anemia, hemorrhagic disorders and venous thromboembolism (VTE) are probably the most important hematological conditions during pregnancy. Moreover, a patient of primary hematological disorder may become pregnant. This would include disorders as varied as thalassemia, sickle cell disease, immune thrombocytopenic purpura (ITP) and chronic myeloproliferative disorders.

ANEMIA INCLUDING THALASSEMIA AND SICKLE CELL DISEASE

During pregnancy, mother’s blood volume expands physiologically. However, this expansion consists of 40–60% increase in plasma volume which is approximately twice the expansion in red cell mass (20–30%). This hydremia of pregnancy results in a drop in hematocrit to 30% with hemoglobin dropping up to 10 g/dL which, hence, forms the lowest limit of normal hemoglobin during pregnancy.

Apart from this “physiological anemia of pregnancy”, other important anemias during pregnancy include:

- Nutritional anemia
- Others.

Nutritional Anemia

During pregnancy, approximately 1 g of additional iron is needed. This is to provide iron for fetal hemoglobin synthesis and to compensate for the bleeding during delivery. A woman, who is pregnant often, has insufficient iron stores to meet the demands of pregnancy. Despite iron deficiency, delivery of iron to the placenta continues. A normal woman is unlikely to have more than 500 mg of iron storage pool and hence prophylactic iron supplementation is essential.

Widely prevalent iron deficiency in both rural and urban population in India makes the matter worse and occasional patient has severe morbidity and even mortality secondary to severe anemia. Emergency blood support is lifesaving in such situation. A mean corpuscular volume (MCV) less than 80 mg/dL and hypochromia of the red blood cells (RBCs) should prompt further studies, including total iron-binding capacity, ferritin levels and hemoglobin electrophoresis if iron deficiency is excluded.

Megaloblastic anemia or even pancytopenia secondary to folic acid deficiency is also extremely common as there is similar escalation in the need for this cofactor. Body stores for folic acid are small and short-lived. The nausea and vomiting further impairs its intake. As it is well-known, folate deficiency during first trimester results in neural tube defects and cleft palate formation in the fetus. Hence, administration of prophylactic folate immediately after diagnosis of pregnancy has become mandatory. An increased MCV can be suggestive of folate deficiency. Determination of serum levels of vitamin B₁₂ and folate may be required.

Dimorphic anemia due to combined iron and folic acid deficiency is, hence, very common. Such patients may have normal MCV and mean corpuscular hemoglobin (MCH) but red cell distribution width (RDW) is grossly elevated and RBC histograms show characteristic curves. Smear examination also helps (Table 1).

Others

Of the uncommon anemias, “common” types include the anemia of renal disease, myelodysplastic syndrome and the anemia of chronic disease. These conditions may be
Thrombocytopenia

Thrombocytopenia, defined as a platelet count of less than 150,000/µL, is common during pregnancy and is diagnosed in approximately 7% of women. The most common thrombocytopenic disorders with pregnancy include:

1. Gestational thrombocytopenia (GT)
2. Immune thrombocytopenic purpura (ITP)
3. HELLP syndrome, preeclampsia and eclampsia
4. Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome.

**Gestational Thrombocytopenia**

Gestational thrombocytopenia is common. It almost never produces overt bleeding needing clinical attention. Platelet count seldom drops below 70,000/cu mm. It is not an indication for any therapeutic intervention including fetal blood sampling. However, before GT is diagnosed, other causes of thrombocytopenia have to be investigated and ruled out. GT could recur in future pregnancies. The diagnosis requires normalization of platelet count after delivery and/or documentation of absence of thrombocytopenia prior to pregnancy. The mechanism remains unclear and the prevalence could be up to 6% of pregnancies.

**Immune Thrombocytopenia Purpura**

Immune thrombocytopenia is a common disorder in young adult women. The diagnosis is one of exclusion, although platelet associated immunoglobulin G antibodies are easily detectable in such patients. The reasons for this include non-specificity of such antibodies and methodological problems related to their documentation. Therapy for ITP during pregnancy includes corticosteroids, intravenous (IV) gamma globulin, second trimester splenectomy, care during delivery and postnatal care of the neonatal thrombocytopenia. Corticosteroids (prednisolone) given orally, form the most common modality of effective treatment for majority of such patients, despite their adverse effects. Despite its efficacy, IV gamma globulin is used only if steroids are ineffective, require higher maintenance dose or have unacceptable adverse effects. This relates to the cost of therapy, parenteral mode of administration, need for hospitalization and their short duration of efficacy necessitating repeated administration at two-weekly intervals or so. Intravenous gamma globulin therapy is hence, usually administered just prior to delivery. With availability of these two modalities of treatment, splenectomy, which carries a risk of fetal loss, is rarely required.

*Treatment of ITP:* For patients who do not respond to corticosteroids of IV immunoglobulin as single agents, combinations of these therapies may sometimes be more effective/particularly when steroids are delivered as high-dose pulse therapy, e.g. methyl prednisolone 1 g/day for two consecutive days.

If this approach fails, laparoscopic splenectomy is needed and can be safely performed during mid-second trimester.

In refractory ITP, azathioprine has been safely used during pregnancy in patients with renal transplants and inflammatory bowel disease. Cyclosporine A has also been used safely in pregnancy. These cytotoxic drugs can be used in mid-second trimester and beyond.

Transplacental passage of antiplatelet immunoglobulin G can result in fetal thrombocytopenia. Adverse events secondary to this are unusual in intrauterine life. However, intracranial hemorrhage during delivery and overt bleeding diathesis up to 3 weeks after delivery are known. Fetal scalp vein sampling during labor or umbilical vein sampling before labor is helpful in diagnosing fetal thrombocytopenia which in turn should influence the method of delivery. A fetal platelet count of over 50,000/cu mm is considered adequate for safe vaginal delivery. Previously used maternal antiplatelet antibody level to anticipate fetal thrombocytopenia is obsolete. Newborn’s platelet count from previous pregnancy

is an excellent predictor of the count in subsequent pregnancies. Interestingly, administration of IV gamma globulin to mother does not influence the fetal platelet count but giving of steroids to mother with ITP in the 3 weeks prior to delivery has its positive effect.

**HELLP Syndrome, Preeclampsia and Eclampsia**

HELLP syndrome (hemolysis, elevated liver enzymes and low platelets) may or may not be associated with increased blood pressure, edema or proteinuria. Patients with HELLP syndrome present with malaise and right upper quadrant or epigastric pain.

Preeclampsia and eclampsia are discussed elsewhere at length. Thrombocytopenia forms only a part of the whole syndrome and rarely requires separate management.

**Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome**

Thrombotic thrombocytopenic purpura is a rare disorder characterized by the pentad—fever, hemolytic anemia, thrombocytopenia, renal disease and central nervous system manifestations. Nonimmune (Coombs’ negative) hemolytic anemia characterized by RBC fragmentation (schistocytosis) and thrombocytopenia are the hallmarks of this rare entity. Except for fever, all other features of TTP are also present in toxemia. Hence, the management of such patient during last trimester usually requires delivery of the infant. Against this, a classical TTP appearing earlier in pregnancy is best treated by plasma exchange or plasma infusion, corticosteroids, antiplatelet drugs, etc.

Hemolytic uremic syndrome is still rarer, and it is managed on similar lines except that role of plasma exchange is unclear while renal failure necessitating dialysis support is common.

These disorders may require maternal management even after the delivery or uterine evacuation.

**von Willebrand’s Disease and Other Genetic Bleeding Disorders**

The most common inherited coagulopathy with pregnancy is vWD with prevalence rate of 0.8–1.3%. von Willebrand’s disease is a common disorder with several subtypes having variable clinical severity needing different management. Fortunately, majority of such patients have significant rise in factor VIII as well as von Willebrand’s factor (vWF) during pregnancy, and hence safe delivery without specific support is common. This, however, does not apply to the rare type 3 vWD where vWF or cryoprecipitate has to be administered before conducting delivery or a cesarean section. The support has to continue for 5–7 days after the delivery. Prenatal sampling of fetal blood helps in identifying the affected infant, and hence vaginal delivery is permissible for unaffected infant. Another subtype, i.e. type 2B, has an additional complexity in the form of gradually worsening thrombocytopenia during pregnancy. Such patients need vWF/cryoprecipitate and not platelet transfusion to support their delivery. Most of the other subtypes of vWD can be helped by infusing desmopressin, which increases endogenous vWF and factor VIII level.

Patients with vWD have an additional problem of delayed bleeding after delivery because of rapid normalization of vWF and factor VIII levels to a nonpregnant deficient state. Such patients would need desmopressin/vWF/cryoprecipitate support.

Other inherited coagulopathies are relatively rare. Factor concentrates or fresh frozen plasma (FFP) during and up to 5 days after delivery is the usual support needed. Coagulation factor level needs to be monitored to decide the replacement protocol and doses.

Factor XIII deficiency is a special problem as it leads to spontaneous recurrent abortions and marked uterine bleeding. Administration of factor XIII concentrates or FFP at regular intervals during pregnancy is helpful.

**Acquired Hemophilia**

Development of acquired inhibitors of coagulation factors, particularly factor VIII is a rare but important disorder in the postpartum period. Nova VII (activated factor VII), prothrombin complex concentrate, activated prothrombin complex concentrate and porcine factor VIII are some of the options available to treat the bleeding complications. Standard factor VIII concentrates in large quantity may also be effective if the inhibitor level is low. Immunosuppressive therapy is also helpful. The problem can rarely recur after subsequent deliveries.

**Disseminated Intravascular Coagulation**

The most common bleeding disorder of hematological origin in obstetric practice is DIC. A rapid and often fatal form of DIC is a dramatic event which may complicate abruptio placentae, amniotic fluid embolism, eclampsia, septic abortion, hypertonic saline and urea induced abortions, etc. A slow DIC, which is usually nonfatal and nowadays infrequent, is seen following intrauterine fetal death.

Disseminated intravascular coagulation during obstetric practice has its origin in the entrance of the thrombogenic products of conception into the systemic circulation. It leads to a combination of thrombosis affecting microcirculation and hemorrhage. Shock, hypoxemia and acidosis are important trigger factors. Correct bedside diagnosis supported by laboratory findings like thrombocytopenia, schistocytosis, prolonged prothrombin time, activated partial thromboplastin time, thrombin time coupled with hypofibrinogenemia and raised D-dimer (a type of fibrinogen degradation products) helps in quick execution of therapeutic measures to decrease maternal mortality and morbidity.
Therapeutic measures include support to vital organs, correction of trigger events, blood component therapy and above all evacuation of uterus. Heparin therapy is not indicated in most forms of DIC complicating pregnancy (except intrauterine fetal death).

HYPERCOAGULABLE STATES

Pregnancy itself is a hypercoagulable state where concentration of clotting factors increase progressively while fibrinolytic capacity drops. In addition, stasis secondary to obstruction of venous return by enlarging uterus, dramatically increase the incidence of VTE in pregnancy and even more during puerperium. The vessels most commonly involved include iliofemoral system and pelvic veins. Occasional fatality can occur secondary to pulmonary embolism, and hence anticoagulation is indicated. As anticoagulation has its own risk, the diagnosis of thromboembolism must be objective. This includes color venous Doppler studies by duplex technology, impedance plethysmography, contrast venography, etc. for the iliofemoral system and ventilation/perfusion scan or pulmonary angiography for pulmonary embolism. Blood test like D-dimer is also helpful.

Inherited (genetic) thrombophilic disorders with pregnancy lead to significant increase in maternal morbidity and mortality secondary to VTE affecting iliofemoral veins, pelvic veins and causing devastating pulmonary emboli. These disorders also lead to fetal wastage, intrauterine growth retardation and premature deliveries.

Antithrombin-III (AT-III) is probably the most well-studied example in this group. Seventy percent of women develop thrombotic events during pregnancy or after delivery. Low-molecular-weight heparin or unfractionated heparin during the first 4 months of pregnancy, oral anticoagulation in the remainder of pregnancy (until 36th week), reintroduction of heparin during last month, and its withdrawal a day before delivery forms the usual protocol. A single infusion of AT-III, 3,500 units just before delivery followed by heparin in the postdelivery period until oral anticoagulation is effectively introduced, is also a must.

Protein C deficiency and protein S deficiency are similarly associated with maternal VTE and fetal wastage. Twenty-five percent of pregnant women with protein C deficiency develop DVT while the exact incidence with protein S deficiency remains unclear. Such mothers require management similar to those with AT-III deficiency.

Factor V Leiden is the most common cause of activated protein C resistance (APC resistance). This mutation, in heterozygous state, is probably the most common cause of hypercoagulable state both in Caucasians and Indians. Prothrombin mutation and hyperhomocysteinemia secondary to methylenetetrahydrofolate reductase may be co-inherited with APC resistance or other prothrombotic disorders exaggerating the risk of VTE and fetal wastage.

Universal screening of pregnant women for these prothrombotic disorders is not recommended. However, those with a personal history of VTE, family history of VTE or unexplained recurrent fetal wastage are candidates for such screening.

Thrombophilic mothers secondary to genetic predisposition may require lifelong anticoagulation, insertion of inferior vena cava filters and regular monitoring of International Normalized Ratio. Thrombolytic therapy during pregnancy is contraindicated due to risk of severe hemorrhage while antiplatelet drugs (aspirin and others) are ineffective.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME AND SYSTEMIC LUPUS ERYTHEMATOSUS

Lupus anticoagulants (LA) and anticardiolipin antibody (ACA) are the laboratory hallmark of relatively common antiphospholipid antibody (APA) syndrome, the most threatening manifestations of which include first trimester abortions and fetal deaths in second as well as third trimesters.

Lupus anticoagulants are immunoglobulins that prolong phospholipid dependent coagulation tests, the most sensitive of which include Kaolin clotting time and dilute Russell viper venom time. ACA are immunoglobulin G or immunoglobulin M antibodies, which are detectable using immunological techniques, i.e. enzyme-linked immunosorbent assay or radioimmunoassay. Occasionally, Venereal Disease Research Laboratory (VDRL) test, a test for syphilis, is also positive (biological false-positive test).

Patients with antiphospholipid antibody (APA) syndrome may develop both arterial and venous thrombosis as well as thrombocytopenia. The mechanism is complex, and it includes prostacyclin inhibition acquired APC-resistance, reduced annexin V levels, acquired deficiency of protein C and free-protein S, etc. The fetal wastage is secondary to a thrombotic process involving the decidual and placental vessels.

Antiphospholipid antibody syndrome could be primary or secondary with systemic lupus erythematosus (SLE) being the most common systemic collagen vascular disease as an underlying illness. Patients with APA syndrome may go on to develop SLE. Similarly, patients with SLE may develop APA syndrome later on. Those affected by APA syndrome may have only LA or only ACA positivity in vitro, and many of these patients may have either clinical evidence of SLE or only serological tests positivity (e.g. antinuclear antibody, anti-dsDNA antibody, etc.).

It is recommended that all women with more than two abortions (specially beyond first trimester), unexplained stillbirths, intrauterine fetal deaths, etc. should be screened for APA syndrome by both LA and ACA testing (Table 2).
Optimal treatment for pregnant women with APA syndrome is undetermined. The use of aspirin and/or prednisolone to reverse the poor outcome has not been validated in placebo-controlled trials. Use of low-molecular-weight heparin as well as unfractionated heparin is a success story among obstetricians, hematologist and neonatologists. Treatment is successful in delaying delivery until it can be terminated. Occasional patient may avoid therapeutic intervention for chronic myelogenous leukemia until delivery as well.

### LEUKEMIA/LEUKEMOID REACTIONS/LEUKOCYTOSIS

Pregnancy itself can occasionally elevate white blood cell count with even shift to left resulting into occasional metamyelocyte and myelocyte in peripheral blood film. Döhle bodies may also be present, and this may create confusion with respect to infections. The mechanism of elevated leukocyte count is unclear but may be related to alterations in cytokines or steroid metabolism.

Leukemia with pregnancy is a rare event and the management is influenced by the stage of pregnancy and family wish. As the first trimester is the most active stage of organogenesis, pregnancy is usually terminated. Spontaneous abortions and fetal losses are also common in such patients. Chronic leukemias may be managed by leukapheresis as successful delaying device until delivery is possible. Chronic myeloid leukemia may also be manageable with α-interferon. There are case reports where successful deliveries without any complications have occurred despite chemotherapy for leukemia and lymphoma during later part of pregnancy. Surprisingly, compounds like ATRA (all-trans-retinoic acid) for treatment of acute promyelocytic leukemia have also been used without fetal complications. Imatinib mesylate has been tried with successful results for treatment of chronic myelogenous leukemia.

### CHRONIC MYELOPROLIFERATIVE DISORDERS

#### Essential Thrombocythemia

This may lead to development of placental infarcts, fetal growth retardation or fetal loss. Monitoring such pregnancies with Doppler ultrasound studies of placental blood flow may help in deciding the need to reduce platelets. Aspirin with or without dipyridamole has been used with success and so is α-interferon. Plateletpheresis has been performed just prior to delivery as well.

#### Polycythemia Vera

Untreated, polycythemia vera with pregnancy leads to poor perinatal outcome with frequent fetal losses. Phlebotomy and judicious use of iron form the mainstay of treatment. Hematocrit must be kept below 40%. Associated thrombocytosis may also create problem. Aspirin or even heparin in perinatal period have been used with success and so is α-interferon. Plateletpheresis has been performed just prior to delivery as well.

#### Chronic Myeloid Leukemia

Once again, α-interferon has been used as the mainstay of treatment. Pregnancies during first trimester may also be terminated. Occasional patient may avoid therapeutic intervention for chronic myeloid leukemia until delivery.

#### Paroxysmal Nocturnal Hemoglobinuria

Cortical venous thrombosis, hepatic and portal vein thrombosis as well as iliofemoral thrombosis are commonly associated with pregnancy in a patient of paroxysmal
nocturnal hemoglobinuria. Low-molecular-weight heparin or low-dose unfractionated heparin during the period of bed confinement is an effective preventive measure. Both hemolytic crises and marrow aplasia are known to worsen during pregnancy. Packed cells support to maintain hematocrit of 40% is desirable. However, this could lead to neonatal isoimmune hemolysis secondary to maternal sensitization.

REFERENCES

INTRODUCTION

The hemoglobinopathies are red blood cell (RBC) disorders which result either from the synthesis of structurally abnormal Hb chains (the Hb variants) or from the defective synthesis of Hb chains (the thalassemia syndromes). These inherited genetic disorders are inherited in Mendelian recessive manner so that persons with the carrier or traits are generally healthy. Patients manifesting clinically significant disease may be homozygous for any one condition or can be heterozygous for two or more hemoglobinopathy genes which interact.

The hemoglobinopathies are result of mutation and deletion in and around the globin genes on chromosome 16 and 11.

SICKLE CELL HEMOGLOBINOPATHIES

Sickle cell disease is one of the most common monogenic disorders over the world, which is associated with lifelong morbidity and reduced life expectancy. Sickle cell hemoglobinopathies or sickle cell disease is a collective name for group of conditions causing clinical symptoms including all those abnormalities resulting from an alteration in structure, function, or production of hemoglobin. Hemoglobin S (HbS) results from substitution of thymine for adenine in the beta-globin gene, which leads to the substitution of the neutral amino acid valine for the negatively charged glutamic acid at the sixth position from the N-terminus in the beta-chain. Hemoglobin C (HbC) results from a lysine substitution for glutamic acid (Fig. 1).

Major sickle disorders with severe clinical symptoms include sickle cell anemia (HbSS), sickle cell hemoglobin C (HbSC) disease, and sickle cell beta-thalassemia (HbS beta-thalassemia).

Minor disorders include hemoglobin C disease (HbAC), hemoglobin SE (HbSE), hemoglobin SD (HbSD), and hemoglobin S-memphis (HbS-memphis). Heterozygosity for hemoglobin A and hemoglobin S (HbAS) is the most common disorder. HbS is also known as sickle cell trait and occurs in 1 in 625 African Americans. HbS is also found in other populations, such as Greeks, Italians (particularly Sicilians), Turks, Arabs, Southern Iranians, and Asian Indians.

Etiopathogenesis

- Sickle cell hemoglobin (HbS) is a variant of the β-chain of hemoglobin. Sickling of the red cells occurs particularly in response to hypoxia, cold, acidosis and dehydration.
- When deoxygenated, HbS molecules undergo aggregation and polymerization. Initially, the red cell cytosol converts from a freely flowing liquid to a viscous gel as HbS aggregates. With continued deoxygenation, aggregated HbS molecules assemble into long needle-like fibers within red cells, producing a distorted sickle or holly leaf shape. These permanently damaged RBCs are then removed by the reticuloendothelial system, with the average RBC lifespan reduced to 17 days. The result is a chronic compensated anemia, with Hb typically measuring between 6.5 g/dL and 9.5 g/dL.
- The sickle shape also results in altered motion through the microvasculature. This altered motion can predispose the patient to vascular stasis, hypoxia, acidosis, and increased production of 2, 3-diphosphoglycerate, which perpetuates the cycle by resulting in further deoxygenation and thus, more sickling. The microvascular injury can result in ischemic necrosis and end-organ infarction. Organs affected by chronic sickling include the spleen, lungs, kidneys, heart, and brain. Patients with sickle cell anemia are functionally asplenic. Therefore, immunization for
encapsulated organisms should be a consideration. Likewise, aggressive treatment should be instituted when encapsulated bacterial infections are diagnosed in sickle cell disease.

Rate and degree of sickling is affected by following factors:
- Most important is amount of HbS and its interaction with other hemoglobin chains in the cell
- Length of time: red cells are exposed to oxygen tension
- A decrease in pH reduces the oxygen affinity of hemoglobin hence more deoxygenation
- Rate of HbS polymerization is strongly dependent upon the Hb concentration per cell or mean corpuscular hemoglobin concentration (MCHC).

**Clinical Features**

**Effect on Pregnancy (Table 1)**
- In addition, Chakravarty and co-workers (2008) reported that sickle cell disease was associated with significantly increased odds ratios for renal failure, various forms of gestational hypertension, and fetal-growth restriction.
- There is increased incidence of abortion, intrauterine growth restriction and prematurity. Fetal distress and perinatal mortality is increased, four to six folds.
- Close observation is recommended at 32–34 weeks; obtain pregnant patient’s blood cell count, to detect hemoglobin level, infection, and serial ultrasonography to monitor fetal growth.
- Crisis complicates about 35% of pregnancies. Painful crisis during pregnancy should be distinguished from ectopic pregnancy, placental abruption, pyelonephritis, appendicitis, cholecystitis or other serious obstetrical or medical problems that cause pain, anemia or both.
- Anemia is not marked, hemoglobin concentration falls below 7 g/dL only if there is presence of infection or nutritional deficiency. Folate supplementation is recommended due to quick turnover of erythrocytes.
- Increased risk of infection is partly due to loss of splenic function. Urinary tract infection (UTI) is twice as common in sickle cell trait.
- Bacteriuria and pyelonephritis are also increased which can precipitate red cell destruction; hematuria is present in few cases. Cardiac dysfunction is present in most of the pregnant women. Preeclampsia and thrombophlebitis, which also increase maternal morbidity and mortality, is estimated to increase by 2.5%.
- Sickling occurs acutely especially late in pregnancy, labor, delivery and early puerperium.
• Acute chest syndrome, this is characterized by fever, tachypnea, pleuritic chest pain, leukocytosis and pulmonary infiltrates. It may be caused by pulmonary infections or infarction from intravascular sickling or thrombosis.

• Splenic sequestration, retinopathy, leg ulcers, aseptic necrosis of bone, renal papillary necrosis, stroke leading to premature death are also seen in some cases.

Investigations and Diagnosis

Diagnosis of hemoglobinopathies is made by hemoglobin electrophoresis. Laboratory tests that may be helpful to distinguish between sickle cell crisis from other cause of pain, are complete blood count (CBC), lactate dehydrogenase (LDH) levels, blood type and cross match, and arterial blood gas determination, as indicated. Suggested scheme of investigation for structural variants is given in Flow chart 1.

Management

During Pregnancy

1. Antenatal surveillance with fetal monitoring every 2–4 weeks, weekly non-stress test (NST) after 32 weeks.

2. Folic acid (5 mg/day) and penicillin prophylaxis to all women.

3. Hemoglobin and mid stream urine should be checked at every visit. Aim is to keep hemoglobin level above 25%, and concentration of HbS should be kept under 60%.

4. Iron supplementation is recommended only in proven cases of iron deficiency.

5. Prophylactic RBC transfusion: Usefulness of transfusion in pregnancy remains unclear. However, it lowers the incidence of painful crisis, and also women with multiple pregnancy are benefited, but multiple transfusion include risk of infection and alloimmunization. In cases with risk of hemoglobin transfusion reaction (HTR) blood transfusion is withheld, and steroids, intravenous immunoglobulin (IVIG) and large doses of erythropoietin are preferable. These have been shown to decrease morbidity in sickle-cell syndromes when given perioperatively and during pregnancy or to prevent strokes in high-risk children. The use of routine prophylactic transfusions during pregnancy remains controversial (American College of Obstetricians and Gynecologists, 2007). They reported a significant decrease in the incidence of painful sickle-cell crises with prophylactic transfusions but no differences in perinatal outcomes. Current consensus is that management should be individualized. Some clinicians choose prophylactic transfusions in women with a history of multiple vaso-occlusive episodes and poor obstetrical outcomes.

6. Assessment of fetal health: Because of the high incidence of fetal-growth restriction and perinatal mortality, serial fetal assessment is necessary. According to the American College of Obstetricians and Gynecologists (2007), a plan for serial sonographic examinations and antepartum fetal surveillance is reasonable. Anyaegbunam and colleagues (1991) evaluated fetal well-being during 39 sickling crises in 24 women. Almost 60% had nonreactive stress tests, which became reactive with crisis resolution, and all had an increased uterine artery systolic-diastolic (S/D) ratio. At the same time, there were no changes in umbilical artery S/D ratios. These investigators concluded that transient effects of sickle-cell crisis do not compromise umbilical,
CHAPTER 9

Hemoglobinopathies in Pregnancy

and hence fetal, blood flow. At Parkland Hospital, we serially assess these women with sonography for fetal growth and amniotic fluid volume changes. Non-stress or contraction stress tests are not done routinely unless complications such as fetal-growth restriction develop or fetal movement is reported to be diminished.

7. Labor and delivery: If a difficult vaginal or cesarean delivery is contemplated, and the hematocrit is less than 20 volumes present, then packed erythrocyte transfusions are administered. Care must be taken to prevent circulatory overload and pulmonary edema from ventricular failure.

During Labor

- Labor should be managed in the same way as for heart disease
- Avoid dehydration, over sedation and acidosis
- Keep patient warm and well oxygenated (avoid over oxygenation)
- Epidural analgesia is of choice during labor. Some recommend elective cesarean section at 36 weeks after partial exchange transfusion. Otherwise, cesarean section should be done for obstetric indications only

- Compatible blood should be kept ready for severe anemia, splenic sequestration and acute chest syndrome
- Circulatory overload is to be avoided.

CONTRACEPTIVE ADVICE

Barrier method is recommended as oral contraception would predispose to thromboembolism. Sterilization is advocated to limit the number of pregnancies, even at young age in parous woman, due to shorter lifespan. Intrauterine contraceptive device (IUCD) is not indicated due to risk of infection.

Progesterone has been long known to prevent painful sickle-cell crises. Because of this, low-dose oral progesterone, progesterone injections, or implants seem ideal. In one study, de Abood and associates (1997) reported significantly fewer and less intense pain crises in women given depot medroxyprogesterone intramuscularly.

EXPERIMENTAL THERAPY

Introduction of fetal hemoglobin (Hbf) by stimulating gamma-chain synthesis appears to be promising treatment for sickling and some thalassemia syndromes as they inhibit polymerization of HbS. Hydroxyurea, 4-azacytidine, as well as recombinant erythropoietin, increase Hbf and decrease sickling.
Other Therapy

There are several therapeutic schemes for sickle-cell patients, some are still experimental (Stuart and Nagel, 2004). Hemoglobin F induction has been studied for sickling and thalassemia syndromes. There are drugs that stimulate gamma-chain synthesis and thus hemoglobin F, which inhibits polymerization of hemoglobin S and resultant sickling. For patients with moderate to severe disease, hydroxyurea increases hemoglobin F production with fewer clinical sickling episodes (Platt, 2008). It may also reduce red cell membrane damage and decrease adherence to endothelium with less vascular damage. At this time, it is unknown if hydroxyurea increases long-term survival (Brawley and co-workers, 008). Experience with hydroxyurea in pregnancy is limited, but is teratogenic in animals (Briggs and colleagues, 2003).

Another cancer drug, decitabine, has been used in patients who are unresponsive to hydroxyurea (DeSimone and colleagues, 2002). Findings from a placebo-controlled trial of inhaled nitric oxide versus placebo suggested benefit for acute vaso-occlusive crises (Weiner and colleagues, 2003).

Hematopoietic cell transplantation as been used as a “cure” for patients with sickle-cell syndromes as well as with thalassemia major. Oringanje and co-workers (2009) performed a Cochrane review and found that only observational studies have been reported. Bone marrow transplantation has been used to provide normal hemoglobin A erythrocyte precursors in pediatric or adult patients with severe disease, and 5-year survival rates exceed 90 percent (Bhatia and Walters, 2008). Cord blood stem cell transplantation from related donors has shown great promise (Pinto and Roberts, 2008). Prenatal diagnosis of sickle-cell disease may allow for in utero stem cell therapy with hemoglobin A cells (Shaaban and Flake, 1999). Perhaps even more intriguing is the possibility that cells taken for prenatal diagnosis from a fetus destined to have sickle-cell anemia can be conditioned to produce hemoglobin A and used for replacement after birth (Ye and co-workers, 2009). Other experimental therapies include a gene therapy technique using a modified β-globin gene that encodes a sickling-resistant protein, which corrected the globin chain in transgenic hemoglobin SS knock-out mice (Pawluk and colleagues, 2001).

THALASSEMIA4.7-10

Introduction

Thalassemias are autosomal recessive genetic disorders of globin chain synthesis. The disease is found throughout the world, but its highest prevalence is in areas endemic for malaria. The syndrome can belong to either of the two groups, the alpha- or beta-thalassemia depending on whether

beta-chain production. HbA is usually absent in these individuals. Elevated levels of HbF can often be found. Beta-thalassemia major, or Cooley anemia, is characterized by precipitation of the excessive alpha chains that results in ineffective erythropoiesis and hemolysis (Fig. 2). The fetus is protected from this because of high levels of HbF; however, after birth, as HbF levels fall, the infant becomes anemic. Although transfusion can prolong life, especially when combined with iron chelation therapy, females with this disorder historically have been infertile. However, with proper care and guidance, pregnancies among women with Thalassemia major are practical and can have successful outcome. These patients require frequent transfusions and chelation treatment with desferrioxamine before pregnancy improves pregnancy outcome. The aim is to achieve a serum ferritin level of 1,000–2,000 ng/mL. Desferrioxamine should be discontinued during pregnancy due to possible harmful effects on the fetus and risk of iron deficiency in the neonate. Vitamin usually given with chelation should also be stopped as it increases the absorption of iron.

**Beta-Thalassemia Minor**
It occurs in individuals who are heterozygous for the gene mutations and therefore have variable production of the beta globin chain. Sickle cell trait may coexist with thalassemia
minor. It presents as profound microcytosis and hypochromia with target cells but only minimal or mild anemia.

Hematological findings
- Mean corpuscular volume rarely more than 75 fL, i.e. low but normal MCHC
- Hematocrit rarely less than 30–33%
- Elevated HbA (3.5–7.5%) with or without raised HbF
- Serum iron and total iron-binding capacity (TIBC) are normal or elevated.

The hemoglobin concentration is typically 8–10 g/dL late in the second trimester. There is no specific therapy for beta-thalassemia minor during pregnancy. The outcomes for the mother and fetus are satisfactory. Blood transfusions are seldom indicated except for hemorrhage. Prophylactic iron and folate are administered in daily doses of 60 mg and 1 mg, respectively. Parenteral iron therapy is contraindicated.

Beta-Thalassemia Intermedia

There is severe mutation on one allele or mild mutation in both. Hemoglobin level is usually between 6 g/dL and 9 g/dL.

Diagnosis

An RBC count higher for a given hemoglobin concentration indicates beta-thalassemia trait. Mean corpuscular volume (MCV) less than 80 fL in pregnancy, and MCH less than 25 rules out beta-thalassemia.

The most common methods for diagnosis are:
- NESTROFT
- Screening by electrophoresis or Hb high performance liquid chromatography (HPLC)
- Complete blood count
- HbA2 estimation: Confirming by Hb electrophoresis or gel electrophoresis or high performance liquid chromatography (HPLC). HbA2 is elevated to > 3.5% in thalassemia trait.
- Reverse dot blot analysis (RDV)
- Amplification refractory mutation system (ARMS).
- Each of the above methods has its own advantages and disadvantages. The choice of method depends on the technical expertise available in the laboratory and the population to be studied. It is best practice to have two alternative methods for detecting each mutation.

NESTROFT

Naked eye single tube red cell osmotic fragility test (NESTROFT) is the test used for screening of patients for thalassemia (in hospitals) based on the fact that red cells with large surface area and volume ratio resist lysis in hypotonic saline indicating lower red cell osmotic fragility, suggesting thalassemia trait. If the tube contents are clear then there is no thalassemia. If it is hazy, it signifies thalassemia. The test has sensitivity of 94.4% and a negative predictive value of 97.6%. It costs about ten rupees per test. It is used in mass screening as well as in an antenatal clinic. Patients positive for this test are subjected to electrophoresis.

The pregnant woman testing positive for the thalassemia trait needs her partner to be tested for the same. If he is also positive, there is a need for prenatal diagnosis as there is a 25% chance of homozygous state in the fetus. If both parents are positive, do confirmatory test followed by genetic testing of the fetus by villous biopsy or amniocentesis before 18 weeks of pregnancy. If the fetus is homozygous, termination of pregnancy is advised.

Prevention

Prenatal diagnosis of thalassemia syndrome is available. DNA diagnosis is mainly based on polymerase chain reaction (PCR) amplification of fetal DNA, obtained from chronic villus sampling (CVS) or cordocentesis, which is followed by hybridization to allele specific oligonucleotide probes.

Prenatal Diagnosis of β-Thalassemia Major

Preimplantation blastomere biopsy has been described by Galvani (2000) and Kanavakis (1999) and their associates. Isolation of single nucleated red blood cells from maternal circulation is being explored for prenatal diagnosis of β-thalassemia (Kolialexi and Colleagues, 2007).

REFERENCES

INTRODUCTION

Hypertension is the most common medical problem encountered in pregnancy and remains an important cause of maternal and fetal morbidity and mortality. It complicates up to 15% of pregnancies and accounts for approximately a quarter of all antenatal admissions. The hypertensive disorders of pregnancy cover a spectrum of conditions, of which preeclampsia poses the greatest potential risk and remains one of the most common causes of maternal death.

NORMAL PHYSIOLOGICAL CHANGE IN BLOOD PRESSURE DURING PREGNANCY

Early in the first trimester there is a fall in blood pressure caused by active vasodilatation, achieved through the action of local mediators such as prostacyclin and nitric oxide. This reduction in blood pressure primarily affects the diastolic pressure and a drop of 10 mm Hg is usual by 13–20 weeks gestation. Blood pressure continues to fall until 22–24 weeks when a nadir is reached. After this, there is a gradual increase in blood pressure until term when prepregnancy levels are attained. Immediately after delivery blood pressure usually falls, then increases. Even women whose blood pressure was normal throughout pregnancy may experience transient hypertension in the early postpartum period, perhaps reflecting a degree of vasomotor instability.

DEFINITION OF HYPERTENSION IN PREGNANCY

Hypertension in pregnancy is diagnosed either from an absolute rise in blood pressure or from a relative rise above measurements obtained at booking. The convention for the absolute value is a systolic more than 140 mm Hg or a diastolic more than 90 mm Hg. The definition for a relative rise in blood pressure incorporates either a rise in systolic pressure of more than 30 mm Hg or rise in diastolic pressure of more than 15 mm Hg above blood pressure at booking. Blood pressure must be elevated on at least two occasions and measurements should be made with the woman seated and using the appropriate cuff size (Table 1). Late in the second trimester and in the third trimester, venous return may be obstructed by the gravid uterus and, if supine, blood pressure should be taken with the woman lying on her side. Korotkoff phase I and V (disappearance) should be used, rather than phase IV (muffling), since it is more reproducible and shows better correlation with true diastolic blood pressure in pregnancy. If phase V is not present, phase IV should be recorded. Automated systems for blood pressure measurement have been shown to be unreliable in severe preeclampsia and tend to under record the true value.

Table 1: How to measure blood pressure during pregnancy?

- Mercury sphygmomanometers are preferable to automated blood pressure monitors
- If automated devices are used, they should be calibrated and checked regularly, against a mercury sphygmomanometer
- Use an appropriate sized-cuff
- Woman should be seated or lying at 45° angle, with arm at level of the heart
- Record blood pressure to the nearest 2 mm Hg
- Use phase V Korotkoff sound (sound disappearance) to measure diastolic blood pressure.
There are three types of hypertensive disorders:
1. Chronic hypertension
2. Gestational hypertension
3. Preeclampsia.

Chronic Hypertension

Chronic hypertension complicates 3–5% of pregnancies, although this figure may rise, with the trend for women to postpone childbirth into their 30s and 40s. The diagnosis of chronic hypertension is based on a known history of hypertension prepregnancy or an elevated blood pressure, i.e. 140/90 mm Hg before 20 weeks gestation. However, there are several caveats to this diagnosis. Undiagnosed hypertensive women may appear normotensive in early pregnancy because of the normal fall in blood pressure, commencing in the first trimester. This may mask the preexisting hypertension and when hypertension is recorded later in the pregnancy it may be interpreted as gestational. Sometimes, the diagnosis is only made several months postpartum, when the blood pressure fails to normalize as would be expected with gestational hypertension. Furthermore, preeclampsia can rarely present before 20 weeks gestation and may be misinterpreted as chronic hypertension.

The presence of mild preexisting hypertension approximately doubles the risk of preeclampsia, but also increases the risk of placental abruption and growth restriction in the fetus. In general, when blood pressure is controlled, such women do well and have outcomes not dissimilar to normal women. However, when chronic hypertension is severe (a diastolic blood pressure > 110 mm Hg before 20 weeks gestation) the risk of preeclampsia is as high as 46% with resultant raised maternal and fetal risks.

Gestational Hypertension

Hypertension occurring in the second half of pregnancy in a previously normotensive woman, without significant proteinuria or other features of preeclampsia, is termed as gestational or pregnancy induced hypertension. It complicates 6–7% of pregnancies and resolves postpartum. The risk of superimposed preeclampsia is 15–26%, but this risk is influenced by the gestation at which the hypertension develops. When gestational hypertension is diagnosed after 36 weeks of pregnancy, the risk falls to 10%. With gestational hypertension, blood pressure usually normalizes by 6 weeks postpartum.

Preeclampsia and Eclampsia

Preeclampsia usually occurs after 20 weeks gestation and is a multi-system disorder. It was classically defined as a triad of hypertension, edema, and proteinuria, but a more modern definition of preeclampsia concentrates on a gestational elevation of blood pressure together with more than 0.3 g proteinuria per 24 hours. Edema is no longer included because of the lack of specificity. Preeclampsia may also manifest, with few maternal symptoms and signs, as isolated intrauterine growth restriction (IUGR). Eclampsia is defined as the occurrence of a grand mal seizure in association with preeclampsia, although it may be the first presentation of the condition.

The incidence of preeclampsia is very much influenced by the presence of existing hypertension, although other risk factors are recognized (Table 3). Overall preeclampsia complicates 5–6% of pregnancies, but this figure increases to up to 25% in women with pre-existing hypertension. Eclampsia complicates 1–2% of preeclamptic pregnancies. An estimated 50,000 women die annually from preeclampsia worldwide and morbidity includes placental abruption, intra-abdominal hemorrhage, cardiac failure, and multi-organ failure. The risks to the fetus from preeclampsia include growth restriction secondary to placental insufficiency, and premature delivery. Indeed, preeclampsia is one of the most common causes of prematurity (accounting for 25% of all infants with very low birth weight, < 1,500 g).

PATHOGENESIS OF PREECLAMPSIA

The pathogenesis and manifestations of preeclampsia can be considered in a two-stage model. The primary stage involves:

Abnormal Placentation

In the first trimester, in a healthy pregnancy, the trophoblast invades the uterine decidua and reaches the inner layer of the myometrium. This migration transforms the small musculoelastic spiral arteries into large (four-fold increase in diameter) sinusoidal vessels resulting in a high capacitance, low resistance blood supply to the intervillous space. Although commencing in the first trimester, the change is completed in the second trimester when another wave of trophoblast migration alters the myometrial segments of the arteries. In preeclampsia, these vascular alterations do not occur or they are limited to vessels in the decidua. In addition to the failure of devascularization, the arteries maintain their response to vasomotor influences and undergo accelerated atherosclerosis, which further impairs perfusion to the intervillous space.

The secondary stage of preeclampsia involves:

Conversion of Uteroplacental Maladaptation to Maternal Systemic Syndrome

Conversion of this uteroplacental maladaptation to the maternal systemic syndrome, results in protean manifestations (Table 4). Failure of the normal cardiovascular changes of pregnancy to take place, which results in hypertension, reduction in plasma volume, and impaired perfusion to virtually every organ of the body. There is vasospasm and activation of platelets and the coagulation system, resulting in microthrombi formation. The link between the placenta and the systemic disorder appears to involve endothelial dysfunction and oxidative stress. The management of preeclampsia essentially focuses on recognition of the condition and ultimately the delivery of the placenta, which is curative. Since preeclampsia may arise with few symptoms, all women are screened during pregnancy through regular antenatal care. Those women who are recognized to be at an increased risk have additional screening and more intensive monitoring.

**Table 3: Risk factors for developing preeclampsia**

- Nulliparity
- Multiple pregnancy
- Family history of preeclampsia
- Chronic hypertension
- Diabetes
- Increased insulin resistance
- Increased body mass index
- Hypercoagulability (inherited thrombophilia)
- Renal disease even without significant impairment
- Low socioeconomic status
- Antiphospholipid syndrome (acquired thrombophilia)
- Previous preeclampsia
- Hydatidiform mole
- Black race

**Table 4: Symptoms and signs associated with preeclampsia**

- Hypertension and proteinuria
- Persistent severe headache
- Persistent new epigastric pain
- Visual disturbances (such as blurred vision, diplopia, or floating spots)
- Vomiting
- Hyperreflexia, brisk tendon reflexes
- Epigastric pain or tenderness
- Severe swelling of hands, face, or feet of sudden onset
- Serum creatinine concentration increased (> 110 ~mol/L)
- Platelet count reduced to < 100 × 10^3/L
- Evidence of microangiopathic hemolytic anemia
- Liver enzyme activity elevated

**MANAGEMENT OF HYPERTENSION IN PREGNANCY**

**Prepregnancy Counseling**

Most of the pregnancies are unplanned and thus prepregnancy counseling may not be feasible. In women with chronic hypertension, assessment before conception permits exclusion of secondary causes of hypertension (for example, renal/endocrine), evaluation of their hypertensive control to ensure it is optimal, discussion of the increased risks of preeclampsia, and education about any drug alterations, which would need to be made in the first trimester should they become pregnant. The majority of women with controlled chronic hypertension will, under close supervision and appropriate management, have a successful outcome. Poorly controlled hypertension in the first trimester will significantly increase maternal and fetal morbidity and mortality. It must be stressed that none of the many antihypertensive agents used in routine practice have been shown to be teratogenic and women can safely conceive while taking medication. However, angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) need to be withdrawn in the first trimester since they are fetotoxic. Women who have experienced poor obstetric outcomes in previous pregnancies because of severe preeclampsia, or those at particular risk need to be counseled about the condition and offered prophylactic treatment with low dose aspirin. Since preeclampsia involves endothelial dysfunction and oxidative stress, there is interest in supplementation, with antioxidant vitamins C and E, in the second trimester. A preliminary trial of antioxidant vitamins, in high-risk women, has reported improvements in biochemical markers of endothelial activation together with a reduction...
in preeclampsia and a large, randomized trial is underway (Table 5).

### ANTENATAL CARE

#### General Maternal Care

Blood pressure assessment and the search for proteinuria form the cornerstone of antenatal screening of all pregnant women for preeclampsia. If “white coat” hypertension is suspected, ambulatory monitoring can be helpful as in the non-pregnant population. Those women who have been defined as at increased risk of preeclampsia are monitored more closely, often in a specialized obstetric clinic. Part of the risk assessment includes Doppler ultrasound evaluation of the uterine arteries around the time of the fetal anomaly scan at 20–22 weeks and blood analysis. Rising blood pressure, deranged blood results, and/or the development of significant proteinuria requires enhanced surveillance. Greater than 1+ proteinuria on dip sticks needs to be formally quantified with a 24 hours urine collection or protein:creatinine ratios. The onset of significant proteinuria, in the absence of renal disease, is among the best indicators of superimposed preeclampsia. Many women are initially asymptomatic, or present with non-specific signs of malaise. However, headache, visual disturbance, or abdominal pain are well recognized signs of severe preeclampsia (Table 4).

#### Doppler Assessment of Uterine Arteries

Pulsed wave and color flow Doppler ultrasound examination of the uterine arteries can demonstrate the increased placental vascular resistance, which results from complete or partial failure of trophoblast invasion of the spiral arteries. Uterine artery “Dopplers” are offered to high-risk women at between 20–24 weeks of pregnancy and have useful predictive power. A woman with normal uterine Doppler assessment at 20–24 weeks can be considered to be at low-risk, whereas those with abnormal Dopplers have approximately a 20% chance of developing preeclampsia and require increased vigilance.

#### Fetal Surveillance

Women with both chronic hypertension and preeclampsia are at risk of IUGR. Such women are offered regular fetal ultrasound scans to assess fetal growth, liquor volume, and umbilical artery blood flow. When preeclampsia is severe, and there is a significant risk of delivery before 34 weeks gestation, intramuscular steroids (dexamethasone or betamethasone) are given to the mother to enhance fetal lung maturity in anticipation of a premature delivery.

### WHEN TO TREAT HYPERTENSION DURING PREGNANCY

Significant hypertension must be treated in its own right, regardless of the assumed underlying pathology, largely to reduce the risk of maternal intracranial hemorrhage. The level at which antihypertensive treatment is initiated for non-severe hypertension remains controversial, depending on whether treatment is focused on maternal or fetal wellbeing. Most physicians commence antihypertensive medication when the systolic blood pressure is more than 140–170 mm Hg or diastolic pressure is more than 90–110 mm Hg. Treatment is mandatory for severe hypertension when the blood pressure is 170/110 mm Hg. Once treatment is started, target blood pressure is also controversial, but many practitioners would treat to keep the mean arterial pressure less than 125 mm Hg—for example, a blood pressure of 150/100 mm Hg. Overzealous blood pressure control may lead to placental hypoperfusion, as placental blood flow is not autoregulated, and this will compromise the fetus. Unfortunately, there is no evidence that pharmacological treatment of chronic or gestational hypertension protects against the development of preeclampsia. Changes in diet or bed rest have not been shown to provide maternal or fetal benefit.

All antihypertensive drugs have either been shown, or are assumed, to cross the placenta and reach the fetal circulation. However, as previously stated, none of the antihypertensive agents in routine use have been documented to be teratogenic, although ACE inhibitors and ARBs are fetotoxic. The objective of treating hypertension in pregnancy is to protect the woman from dangerously high blood pressure and to permit continuation of the pregnancy, fetal growth and maturation.

#### Mild-to-Moderate Hypertension

The evidence base for treatment of mild-to-moderate chronic hypertension in pregnancy resides in maternal benefit rather than fetal benefit.
than clear evidence of an enhanced perinatal outcome for the baby. Some women with treated chronic hypertension are able to stop their medication in the first half of pregnancy, because of the physiological fall in blood pressure during this period. However, this is usually temporary, and women are monitored and treatment resumed as soon as necessary.

**First-line Agent**

**Methyldopa**

Methyldopa is a centrally acting agent and remains the drug of first choice for treating hypertension in pregnancy. It has been the most frequently assessed antihypertensive in randomized trials and has the longest safety track record. Long-term use has not been associated with fetal or neonatal problems and there are safety data for children exposed in utero. Women should be warned of its sedative action and this can limit up the titration. The drug may result in an elevation of liver transaminases (in up to 5% of women) or a positive Coomb’s test (although hemolytic anemia is uncommon). Methyldopa should be avoided in women with a prior history of depression, because of the increased risk of postnatal depression.

**Second-line Agents**

These agents should be used when monotherapy with methyldopa is insufficient or when women are unable to tolerate methyldopa.

**Nifedipine**

Nifedipine is popular for the treatment of hypertension in pregnancy and is widely used. It is safe at any gestation. The use of sublingual nifedipine, however, should be avoided to minimize the risk of sudden maternal hypotension and fetal distress, caused by placental hypoperfusion. Abrupt hypotension is potentiated with concomitant magnesium sulfate (used as a treatment or prophylactic agent against eclamptic seizures with severe preeclampsia). Amlodipine has been used in pregnancy but safety data are lacking.

**Oral Hydralazine**

Hydralazine is safe throughout pregnancy, although the occurrence of maternal and neonatal lupus-like syndromes have been reported. Hydralazine is more frequently used as an infusion for the treatment of acute severe hypertension.

**Third-line Agents**

**Alpha- and Beta-adrenergic Blockers**

In the past, β-adrenergic blockers have been highlighted as a class of antihypertensives associated with an increased risk of IUGR. Atenolol in particular has often been singled out. However, in a recent meta-analysis of published data from randomized trials, the presence of IUGR appeared not to be related to the antihypertensive used. Nevertheless, β-adrenergic blockers are still avoided in the first half of pregnancy because of concerns about growth restriction and are viewed as third-line agents for the treatment of hypertension in pregnancy. α Blockers are safe throughout pregnancy and there is wide experience with oxprenolol and labetalol. The safety and efficacy of prazosin in pregnancy has been demonstrated. Doxazosin appears to be safe, although data are limited.

**Thiazide Diuretics**

Thiazide diuretics are used infrequently in pregnancy. The drugs do not appear to be teratogenic and although such drugs abbreviate the plasma volume expansion associated with normal pregnancy, this has not been proven to impair fetal growth. The obstetric community remains reluctant to use these antihypertensive agents because of concern about potentiating the plasma volume contraction, which occurs with preeclampsia. However, women with chronic hypertension who, before conception, responded well to a thiazide diuretic, could have the drug re instituted in pregnancy but it should be withdrawn if preeclampsia develops.

**Drug Treatment of Severe Hypertension**

Severe hypertensive urgency or emergency first-line treatment:
- Labetalol (IV)
- Hydralazine (IV)
- Beta-blockers (IV)
- Nifedipine (PO)

The mortality and morbidity of women with severe hypertension (> 170/110 mm Hg), usually secondary to severe preeclampsia, remains considerable. Because of the circulating plasma volume contraction, women may be very sensitive to relatively small doses of antihypertensive agents (and diuretics), risking abrupt reductions in blood pressure. Good control of hypertension in severe preeclampsia does not halt the progression of the disease, only delivery can do this, but it can reduce the incidence of complications such as cerebral hemorrhage. Management of severe hypertension involves adequate blood pressure control, often using parenteral agents, and “expectant” management by trying to prolong the pregnancy without unduly risking the mother or fetus. In severe cases, only hours or days may be gained. Different units have their preferences for either parenteral hydralazine or labetalol, and some use oral nifedipine. Hydralazine should be given after a colloid challenge to reduce the reflex tachycardia, and abrupt hypotension, precipitated by vasodilatation of a volume contracted circulation. These
women are on a high-risk and should be managed in a high dependency unit setting. They are very sensitive to fluid overload and are at risk of developing noncardiac pulmonary edema, through capillary leak. Severe forms of preeclampsia require admission to intensive care, frequently for respiratory failure or the development of a severe systemic inflammatory response syndrome (SIRS). Seizure prophylaxis, with intravenous magnesium sulfate, may be required in these cases.

**ANTIHYPTERTENSIVE DRUGS TO AVOID IN PREGNANCY**

Antihypertensive drugs to:
- Avoid in pregnancy
  - Thiazide diuretics
- Contraindicated in pregnancy
  - Angiotensin-converting enzyme inhibitors (PO)
  - Angiotensin receptor blockers (PO)
  - Aldosterone antagonists (PO)

Both ACE inhibitors and ARBs are fetotoxic but there are no data to support teratogenicity. Women can thus be reassured that conceiving while taking such agents, particularly ACE inhibitors where the data are strongest, appears to be safe. However, all women of childbearing age treated with these drugs must be informed of the need for drug discontinuation within the first trimester should they become pregnant. The greatest risk to the fetus appears to be associated with exposure in the third trimester, but the earlier the discontinuation the better, hence the need for patient education. A variety of malformations and adverse events have been reported for both ACE inhibitors and ARBs including:
- Oligohydramnios
- Intrauterine growth restriction
- Joint contractures
- Pulmonary hypoplasia
- Hypocalvaria (incomplete ossification of the fetal skull)
- Fetal renal tubular dysplasia and neonatal renal failure.

**ANTIHYPTERTENSIVE TREATMENT POSTPARTUM AND DURING BREASTFEEDING**

Postpartum hypertension is common. Blood pressure typically rises after delivery over the first 5 days. Thus women who experienced hypertension during pregnancy may be normotensive immediately after the birth, but then become hypertensive again in the first postnatal week. The need to obtain hypertensive control may delay discharge. Methyldopa should be avoided postpartum because of the risk of postnatal depression. Our first-line agent is atenolol, plus nifedipine or an ACE inhibitor if another agent is required. Women with gestational hypertension, or preeclampsia, are usually able to stop all antihypertensives within 6 weeks postpartum. Those with chronic hypertension can resume their prepregnancy drugs. Diuretics, however, are usually avoided if the woman wishes to breast feed because of increased thirst. Proteinuria in preeclamptic women will usually remit by 3 months postpartum, in the absence of any underlying renal abnormality. Persistent proteinuria requires further renal investigation.

An accurate estimation of drug passage into breast milk is difficult to individualize since it is influenced by many factors such as the lipid solubility of the drug, protein binding, ionization, molecular weight, and the constituents of milk itself (fat, protein versus water content). However, most antihypertensive agents used in routine practice are compatible with breastfeeding, but safety data for doxazosin, amlodipine, and ARBs are lacking.

**RISK OF RECURRENCE OF HYPERTENSIVE DISORDERS IN A SUBSEQUENT PREGNANCY**

Women who experience hypertension in first pregnancy are at an increased risk in a subsequent pregnancy. Certain factors influence this risk. The earlier the onset of hypertension in the first pregnancy, the greater the risk of recurrence and the type of hypertensive disorder influences recurrence. One study reported a recurrence risk of 19% for gestational hypertension, 32% for preeclampsia, and 46% for preeclampsia superimposed on preexisting chronic hypertension. In addition, severe isolated IUGR is also a risk factor for developing hypertension in a subsequent pregnancy.

**LONG-TERM CARDIOVASCULAR SEQUELAE OF PREGNANCY-INDUCED HYPERTENSION**

Women who develop gestational hypertension or preeclampsia are at increased risk of hypertension and stroke in later adult life. Furthermore, there is evidence of an increased risk of ischemic heart disease (IHD) in women who have experienced preeclampsia or isolated IUGR, together with increased death rates from IHD. At first an association between preeclampsia and an increased risk of IHD in later adult life may appear rather tenuous. However, both conditions are associated with dyslipidemia, insulin resistance, and endothelial dysfunction. It is of interest that the lipid abnormalities which occur in preeclampsia [raised low density lipoprotein (LDL), very low density lipoprotein (VLDL), free fatty acid, and triglyceride values] pre-date the clinical appearance of the condition and endothelial dysfunction continues to be impaired postpartum.

Although there are methodological concerns with some of the data in this area, these apparent late sequelae may
have important public health implications given the relative frequency of pregnancy induced hypertension and may, in future, dictate screening for cardiovascular disease in previously affected women. At the very least, it would seem prudent for such women to have an annual blood pressure measurement. Interestingly, women who go through a pregnancy without developing hypertension are at a reduced risk of becoming hypertensive in later life, when compared to nulliparous women. Pregnancy may offer a window into the future for cardiovascular health of women, which is unavailable in men.

MANAGING HYPERTENSION IN PREGNANCY: KEY POINTS

- Main categories of hypertensive disease in pregnancy: chronic, gestational, preeclampsia
- Preeclampsia remains an important cause of maternal death in the UK
- No antihypertensive has been shown to be teratogenic, but ACE inhibitors and ARBs are fetotoxic
- First-line antihypertensive during pregnancy: Methyldopa
- First-line antihypertensive post partum: Atenolol
- Pregnancy induced hypertension increases the risk of cerebrovascular disease and ischemic heart disease in later life.

BIBLIOGRAPHY

INTRODUCTION

Pregnant women with normal cardiac function can accommodate many alterations in the cardiovascular system that accompanies pregnancy and labor without difficulty. However, in women with cardiac disease, these changes may lead to heart failure, arrhythmias and stroke. Maternal heart disease complicates 0.2–4% of pregnancies and is responsible for 10–25% of maternal deaths. Uterine congestion, insufficient oxygenation, elevated carbon dioxide content of blood may compromise the fetus and may lead to growth restriction and premature labor and delivery. With advances in surgery and medical therapy, more women with congenital heart disease now reach their adult reproductive years and are becoming pregnant more often. The etiology of heart disease has changed from primarily rheumatic to predominately congenital.

Cardiovascular Adaptation to Pregnancy (Table 1)

During pregnancy, complex biochemical, electric and physiologic changes occur that alter the blood volume, myocardial contractility and resistance of the vascular bed.

Cardiac output and blood pressure increases during labor and delivery as a result of pain and uterine contractions. Immediately after delivery, vena caval and aortic compression is relieved and auto transfusion from the emptied and contracted uterus produces further increase in cardiac output. Most hemodynamic changes resolve by 2 weeks postpartum (Table 2). In the presence of underlying heart disease, above changes can compromise maternal life and that of her unborn child.

ECG Changes

• Atrial and ventricular ectopics
• Q wave and inverted T wave in lead III
• ST depression and T wave inversion inferior and lateral leads
• QRS axis leftward shift.

Maternal risk in relation to cardiac disease in pregnancy is shown in Table 3.

A validated cardiac risk score has been shown to predict a woman’s chance of having adverse cardiac complications during pregnancy (Table 4). Each risk factor was given a value of 1 point. The maternal cardiac event rates for 0, 1, and higher than 1 point are 5%, 27%, and 75% respectively.

Fetal Risks

When a pregnant patient or a first degree family member has a congenital heart disease, then the risk for these diseases increases in the fetus. The incidence is 0–10% depending on the specific lesion when the fetus is affected. Approximately 50% have the same anomaly as the mother. Rate of growth restriction and prematurity is increased in pregnant women with cardiac disease.

Cardiac Murmurs

Early to mid-systolic and soft murmurs (grades I–II) are very common during pregnancy (> 90%). These murmurs are rarely associated with cardiac pathology. Systolic murmurs that are loud or long are frequently associated with cardiac pathology. Late systolic, pansystolic and diastolic murmurs are abnormal and require further evaluation by echocardiography.

Mitral Valve Prolapse

It is prevalent in 21% of women in the reproductive age. Palpitation, arrhythmias, chest pain, syncope, fatigue and panic attacks are reported with this condition. Mitral regurgitation is checked by echocardiography. Observe the patient for cardiac arrhythmias, especially supraventricular tachycardia (SVT). These patients should be advised to avoid caffeine, alcohol, betamimetic drugs and tobaccos.

CARDIOVASCULAR DRUGS

Commonly used cardiovascular drug classes and their potential adverse effects during pregnancy are shown in Table 5.
### MANAGEMENT OPTIONS

#### Prepregnancy
- Obstetrician and cardiologist in collaboration
- Discussion of maternal and fetal risks
- Discussion of safe and effective contraception
- Evaluate current cardiac status
- Optimize medical and surgical management
- Advise against pregnancy with certain conditions.

#### Prenatal
- Assess functional class of heart disease (Table 6)
- Termination is an option with some conditions
- Joint management with a cardiologist
- Optimize medical management
- Avoid or minimize aggravating factors
- Anticoagulation for certain conditions, discuss the risks and benefits of continued warfarin therapy versus changing to subcutaneous heparin
- Anesthesiology

**Abbreviations:** AF, atrial fibrillation; CHF, congestive heart failure; CNS, central nervous system; DVT, deep vein thrombosis; HCM, hypertrophic cardiomyopathy; MI, myocardial infarction

### Table 6: New York Heart Association Cardiac Functional Classification

**Class I:** No limitations of physical activity; ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.
**Class II:** Slight limitation of physical activity; ordinary physical activity results in fatigue, palpitation, dyspnea or anginal pain.
**Class III:** Marked limitation of physical activity less than ordinary activity; results in fatigue, palpitation, dyspnea or anginal pain.
**Class IV:** Inability to perform any physical activity; without discomfort; symptoms of cardiac insufficiency or anginal syndrome may be present even at rest and any physical activity increases discomfort.

### Table 7: American Heart Association recommendation for endocarditis prophylaxis

**High Risk**
- Prosthetic cardiac valves, including bioprosthetic and homograft valves
- Previous bacterial endocarditis
- Complex cyanotic congenital heart disease (e.g. single ventricle states, transposition of the great arteries, Tetralogy of Fallot)
- Surgically constructed systemic pulmonary shunts or conduits.

**Moderate Risk**
- Most other congenital cardiac malformations (other than those listed above and below)
- Acquired valvular dysfunction (e.g. rheumatic heart disease)
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with valvular regurgitation or thickened leaflets.

- Avoid mental and physical stress, consider epidural
- Labor in the left lateral and upright positions
- Monitor electrocardiogram; more invasive monitoring is needed with certain conditions
- Full resuscitation facilities should be available
- Provide continuous fetal heart rate monitoring
• Assisted second stage with certain conditions
• Avoid ergotamine for the third stage.

**Postnatal**

• Vigilance for cardiac failure
• Avoid fluid overload
• Continued intensive care
• Discuss safe and effective contraception.

**CONGENITAL HEART DISEASE**

The incidence of congenital heart disease in pregnancy is increasing as women with more severe defects, who underwent corrective surgery as children, are now able to have children themselves. The most common congenital heart diseases in pregnancy are patent ductus arteriosus (PDA), atrial septal defect (ASD) and ventricular septal defect (VSD). Together these account for about 60% of cases.

**ATRIAL SEPTAL DEFECT**

• Most common congenital heart defect in women
• Usually well tolerated in pregnancy
• Potential risk of paradoxical embolism, but risk is low
• Women may deteriorate and become hypotensive if there is an increase in the left-to-right shunt following blood loss at delivery. This causes a drop in left ventricular output and coronary blood flow
• Supraventricular arrhythmias are uncommon before the age of 40 years but may rarely complicate pregnancy.

**VENTRICULAR SEPTAL DEFECT**

• Increased volume load of left ventricle
• Usually well tolerated in pregnancy unless the woman has Eisenmenger’s syndrome.

**CYANOTIC CONGENITAL HEART DISEASE**

Cyanosis carries significant risks for mother and fetus. Problems include:
• Worsening cyanosis because of increased right-to-left shunting secondary to falling peripheral vascular resistance
• Thromboembolic risk increased because of polycythemia (secondary to hypoxemia)
• Increased risk of fetal loss (especially if oxygen saturation > 80–85%) and increased risk of intrauterine growth restriction. Their chance of a livebirth is more than 20%
• Associated pulmonary hypertension.

*Pregnancy outcome is improved if:*
• Resting oxygen saturation more than 85%
• Hemoglobin less than 18 g/dL
• Hematocrit less than 55%

**EISENMENGER’S SYNDROME**

This results when pulmonary hypertension develops secondary to a large left-to-right shunt such as a VSD, and the shunt is reversed to become right-to-left shunt with consequent cyanosis. Pulmonary hypertension is dangerous and may be primary or secondary to lung disease or Eisenmenger’s syndrome. Maternal mortality is 40%. The danger relates to fixed pulmonary vascular resistance and an inability to increase pulmonary blood flow with refractory hypoxemia. Most deaths can be attributed to thromboembolism, hypovolemia or preeclampsia.

**Management**

Women with severe pulmonary hypertension or Eisenmenger’s syndrome should be advised to avoid pregnancy or, in the event of unplanned pregnancy, to have a therapeutic termination. If such advice is declined, multidisciplinary care and elective admission for bed rest, oxygen and thromboprophylaxis are recommended.

**PULMONARY HYPERTENSION**

Maternal mortality rate is very high (50%) when pulmonary hypertension is associated with pregnancy. It can be primary (idiopathic) or secondary to long standing ASD/VSD, PDA or mitral stenosis. Increase in cardiac output during labor, delivery and postpartum period may lead to right sided heart failure or myocardial ischemia, leading to arrhythmias, ventricular failure and sudden death. Chronic maternal hypoxia leads to intrauterine growth restriction and premature delivery. Pregnancy should be discouraged and permanent sterilization should be considered. If pregnancy occurs, termination should be offered because of maternal risks.

**MARFAN’S SYNDROME**

Marfan’s syndrome is inherited as an autosomal dominant disorder. About 80% of patients with Marfan’s syndrome have cardiac involvement, most commonly:
• Mitral valve prolapse
• Mitral regurgitation
• Aortic root dilatation.

In pregnancy, this syndrome carries the risk of aortic dissection and aortic rupture.

*Predictors for dissection and rupture include:*
• Preexisting or progressive aortic root dilatation (10% risk if root > 4 cm)
• Positive family history of dissection or aortic rupture.

**Management**

• Pregnancy is contraindicated if the aortic root is more than 4–4.5 cm
Patients at high-risk (and particularly if root > 4.5 cm) should be offered aortic root replacement prior to pregnancy. β-blockers have been shown to reduce the rate of aortic dilatation and the risk of complications in patients with Marfan’s syndrome. Regular echocardiograms should be carried out to assess aortic root diameter. Elective cesarean section is usually recommended for women with aortic roots showing progressive enlargement or size more than 4.5 cm.

**PERIPARTUM CARDIOMYOPATHY**

Development of heart failure in the last month of pregnancy and 5 months postpartum in the absence of a known cause and without any heart disease prior to the last month of pregnancy (Fig. 1).

**Risk Factors**
- Multiple pregnancy
- Pregnancy complicated by hypertension
- Multiparity
- Advanced maternal age
- Afro-Caribbean race.

**Signs and Symptoms**
- Dyspnea
- Palpitations
- Pulmonary and/or peripheral edema
- Symptoms relating to peripheral or cerebral emboli
- Tachycardia
- Congestive cardiac failure
- Dysrhythmias
- Signs of pulmonary, cerebral and systemic embolization
- Systemic embolism occurs in 25–40% of those affected by peripartum cardiomyopathy, and ischemic stroke in about 5%.

**Diagnosis**
This requires echocardiography. The diagnostic criteria are:
- Left ventricular ejection fraction (LVEF) less than 45%
- Fractional shortening less than 30%
- Left ventricular end-diastolic pressure (LVDP) more than 2.7 cm/m²

**Management**
- Elective delivery, if antenatal
- Thromboprophylaxis. Anticoagulants are mandatory if there is severely impaired left ventricular dysfunction, intracardiac thrombus or arrhythmias
- Conventional treatment for heart failure including diuretics, vasodilators (hydralazine and/or nitrates), cardioselective β-blockers (bisoprolol) or β-blockers with arteriolar vasodilation action (carvedilol, digoxin, inotropes) and, after delivery, angiotensin converting enzyme (ACE) inhibitors
- Cardiac transplantation may be the only option in severe cases unresponsive to conventional and full supportive management.

**Prognosis and Recurrence**
- Maternal mortality rate is reported to be 20–50%
- About 50% of patients make spontaneous and full recovery
- Prognosis depends on normalization of left ventricular size and function within 6 months after delivery
- Women should be counseled against further pregnancy if left ventricular size or function does not return to normal, since there is a significant risk of recurrence, worsening heart failure (50%) and death (25%) in subsequent pregnancies
- For those whose cardiomyopathy resolves, the recurrence risk is not known but appears to be lower (0–25%).

**MYOCARDIAL INFARCTION**

Myocardial infarction is becoming more frequent as older women are becoming pregnant. The worldwide maternal death rate from acute myocardial infarction is over 20%.

**Risk Factors**
- Smokers
- Diabetes
- Obesity
- Family history of ischemic heart disease
- Hypertension
- Hypercholesterolemia
- Multigravidas older than 33 years.
Acute myocardial infarction occurs most commonly in the third trimester, and affects the anterior wall of the heart. In pregnancy, the underlying cause of infarction is more likely to be due to non-atherosclerotic conditions such as coronary artery thrombosis and dissection of coronary arteries. 

**Management**

- Management for acute ischemia and infarction is as for the nonpregnant woman, with heparin, β-blockers and nitrates.
- Low-dose aspirin (75–150 mg/day) is safe for use in pregnancy and should be continued or commenced in pregnancy for primary and secondary prophylaxis. In the acute management of myocardial infarction, 150–300 mg can be given.
- Thrombolytic (intravenous and intracoronary) therapy has been used successfully.
- Coronary angiography is usually appropriate to determine the underlying cause of the infarction and percutaneous transluminal angioplasty and stenting may be used if appropriate.
- Statins should be discontinued prior to pregnancy as, in human pregnancy, there is an increased risk of central nervous system and limb defects.

**MECHANICAL HEART VALVES**

Women with metal heart valve replacements need life-long anticoagulation and this must be continued in pregnancy because of the increased risk of thrombosis.

**Management**

The interest of the mother and fetus are in conflict. Continuation of warfarin affords the mother the lowest risk of thrombosis, whereas for the fetus warfarin is associated with an increased risk of teratogenesis, miscarriage, stillbirth, and intracerebral bleeding.

High-dose subcutaneous low-molecular-weight heparin (LMWH) is safe for the fetus but is associated with a higher risk of thrombosis for the pregnant woman.

The choice of anticoagulation regimen will depend on:

- Position of the prosthesis
- Type of valve replacement
- The number of mechanical valves. Two valves give a higher risk of thrombosis
- Previous history of embolic events
- The dose of warfarin required to maintain a therapeutic INR. The risk of embryopathy and fetal loss are increased in women requiring more than 5 mg
- Patient’s choice. Some women are unhappy to accept any additional risk to the fetus.

The anticoagulant regimes are:

- Warfarin throughout pregnancy
- Heparin between 6 weeks and 12 weeks gestation followed by warfarin
- Heparin throughout.
  When heparin is used, low-dose aspirin should be added as an adjunctive antithrombotic therapy.
  Subcutaneous heparin should be discontinued for labor and delivery. The dose of intravenous heparin is reduced to prophylactic levels.
  Full anticoagulant doses of heparin should be resumed after delivery.
  Warfarin may be restarted 3–5 days following delivery.
  In the event of an urgent need to deliver a fully anticoagulated patient, warfarin may be reversed with fresh frozen plasma (FFP) and vitamin K, and heparin and LMWH with protamine sulfate.

**ACQUIRED HEART DISEASE**

Worldwide, the acquired heart disease most likely to affect women wishing to have children is rheumatic heart disease. This is caused by rheumatic fever, which damages one or more of the heart valves. Mitral stenosis accounts for 90% of rheumatic heart disease in pregnancy.

**MITRAL STENOSIS**

In pregnancy, women may deteriorate secondary to tachycardia, arrhythmias or the increased cardiac output. The commonest complication is pulmonary edema secondary to increased left atrial pressure and precipitated by increased heart rate or increased volume (such as occurs during the third stage of labor).

**Poor prognostic features for development of pulmonary edema include:**

- Severe mitral stenosis as assessed by valve area less than 1 cm
- Presence of moderate-to-severe symptoms prior to pregnancy.

**Management**

Women with severe mitral stenosis should be advised to delay pregnancy until after balloon, open or closed mitral valvotomy. Beta-blockers decrease heart rate and the risk of pulmonary edema, but if medical therapy fails or for those with severe mitral stenosis, balloon mitral valvotomy can be performed safely in pregnancy. Supine and lithotomy positions should be avoided in labor and delivery.

**ARRHYTHMIAS**

A sinus tachycardia requires investigation for possible underlying pathology such as blood loss, infection, heart failure, thyrotoxicosis or pulmonary embolus, but no treatment is required if such causes are excluded. The most common arrhythmia encountered in pregnancy is SVT. An SVT that does
not respond to vagal maneuvers may be safely terminated in pregnancy with adenosine.

**GENETIC COUNSELING**

- The risk of the fetus having a congenital heart defect is higher, if the mother rather than the father has congenital heart disease. Overall, the risk is about 2–5%
- The level of risk depends on the specific lesion and is higher for outflow tract lesions
- In women with aortic stenosis and ASD, the risk of an ASD in the fetus is about 5–10%, for aortic stenosis, the risk is highest (18–20%)
- Both Marfan’s syndrome and hypertrophic cardiomyopathy (HOCM) have autosomal dominant inheritance.

**HEART DISEASE IN PREGNANCY: KEY POINTS**

- Women with significant heart disease need multidisciplinary care in a specialist center by obstetricians, cardiologists and anesthetists with expertise in the care of heart disease in pregnancy
- Discuss safe and effective contraception, if pregnancy contraindicated
- Assess functional class of heart (New York Heart Association classification)
- Palpitations, extrasystoles and systolic murmurs are extremely common in pregnancy and mostly benign.
- Contraindications to pregnancy include:
  - Dilated aortic root more than 4.5 cm
  - Severe left heart obstruction from critical mitral or aortic stenosis
  - Severe impairment of left ventricular function
  - Pulmonary hypertension and fixed pulmonary vascular resistance.
- Careful prepregnancy counseling is vital for a pregnant woman with mechanical heart valves as anticoagulation in these cases is associated with risks to the mother and/or fetus
- Peripartum cardiomyopathy should be treated with conventional heart failure therapy (including thromboprophylaxis) with the exception that ACE inhibitors are withheld until after delivery
- Fetal surveillance and detailed fetal cardiac ultrasonography if the patient has congenital heart disease
- Serial ultrasound examinations usually begin at 32 weeks unless there is presence of fetal or maternal complications
- Elective induction may be necessary for maternal or fetal indication
- Vigilance for cardiac failure and avoid fluid overload
- Labor should be in left lateral and upright position with continuous fetal heart rate monitoring
- Assisted second stage with certain conditions such as severe mitral stenosis
- Avoid ergotamine for third stage.

**REFERENCES**

INTRODUCTION

Depending on the specific population abnormal maternal glucose regulation occurs in 3–10% of pregnancies and 80–90% of these are detected during pregnancy, while the rest are overt or pregestational. It is the most common medical complication of pregnancy. Diabetes during pregnancy is associated with a high perinatal mortality and morbidity. Infants of mothers with pre-existing diabetes experience double the risk of serious injury at birth, triple the likelihood of cesarean delivery and quadruple the incidence of newborn intensive care unit admissions.

Maternal Fetal Metabolism in Normal Pregnancy

With each feeding the pregnant woman undergoes a series of maternal hormonal actions leading to rise in blood glucose, free fatty acids, ketones and triglycerides in response to glucose. There is secondary secretion of pancreatic insulin, glucagon, somatomedins and adrenal catecholamines, so as to provide glucose to the fetus and mother. Pregnant women tend to develop hypoglycemia (mean plasma glucose, 65–75 mg/dL) between meals and during sleep because fetus continues to draw glucose, even during periods of fasting. This hypoglycemia becomes increasingly marked as pregnancy progresses, because the glucose demand of the fetus increases.

Rising levels of placental steroid and peptide hormones (estrogen, progesterone, chorionic somatomammotropin) during the 2nd and 3rd trimester produce insulin resistance and insulin sensitivity also falls by 50%. Increased binding of insulin to adipocytes and hepatocytes results in insulin resistance. Thus, with each feeding the demand for insulin secretion escalates progressively during pregnancy. If maternal pancreatic insulin response is inadequate then maternal and fetal hyperglycemia results.

Surging maternal and fetal glucose levels are accompanied by episodic fetal hyperinsulinemia which in turn promotes excess nutrient storage, resulting in macrosomia. Conversion of excess glucose into fat causes depletion in fetal oxygen levels, which are accompanied by surges in adrenal catecholamines, which, in turn, cause hypertension, cardiac remodelling and hypertrophy, stimulation of erythropoietin, red blood cell hyperplasia and increased hematocrit which results in vascular sludging, poor circulation, ischemia of vital organs and postnatal hyperbilirubinemia.

During normal pregnancy mean fasting blood sugar (FBS) level decline progressively to a low value of about 74 mg/dL and peak postprandial blood sugar to 120 mg/dL.

Fetal Morbidity with Diabetes during Pregnancy

There is a strong association between the degree of glycemic control prior to pregnancy, 3–6 weeks after conception, 2nd and 3rd trimester of pregnancy and miscarriage, birth defects, macrosomia with central obesity, in utero growth restriction, growth acceleration, etc. extending into childhood and adult life. The rates of various morbidities associated with diabetes in pregnancy are shown in Table 1.
Congenital Malformations

Its rate is about 5–10 times that in nondiabetics and accounts for approximately 10–50% of perinatal mortality. The anomalies may involve skeletal, central nervous system (CNS), cardiac, renal, gastrointestinal and other systems. The most common being cardiac [ventricular septal defect (VSD), atrial septal defect (ASD), etc.]. Risk factors are poor preconceptual glycemic control, early onset of disease, ketoacidosis, vasculopathy and hypoxia. Factors influencing the development of congenital malformations are shown in Table 2.

Growth Acceleration, Fetal Obesity and Central Obesity

Macrosomia (birth weight > 4,000 g or that exceeds 90th percentile for gestational age) occurs in 15–45% of cases. These fetuses have a unique pattern of overgrowth (central obesity). The abdominal circumference growth rises above normal after 24 weeks. These newborns face the risk of hypoglycemia, neonatal jaundice, birth trauma, shoulder dystocia, erb’s palsy, prolonged labor, asphyxia and meconium aspiration. Excessive body fat stores, stimulated by excessive glucose delivery during diabetic pregnancy often extend into childhood and adult life. By 10–16 years, these offspring’s have a 19.3% rate of impaired glucose tolerance, diabetes mellitus (2–3%) in later life, neurological deficit (4%) and childhood obesity (50%).

Growth Restriction

Pregnant diabetic patients with vascular disease (retinal/renal or chronic hypertension) are at risk for growth restriction and preterm birth.

Role of Glucose Levels and Maternal Obesity

Fetal birth weight correlates best, with 2nd and 3rd trimester postparandial blood sugar levels. Maternal obesity has a strong and independent effect on fetal macrosomia.

Maternal Morbidity: Retinopathy, Nephropathy, Chronic Hypertension and Preeclampsia

In women with severe to moderate renal impairment (creatinine > 125 µmol/L) and hypertension there is a significant risk of permanent decline in renal function. There is a 2-fold risk of progression of diabetic retinopathy and the risk is higher for women with type 1 diabetes. Thus, renal function test and full retinal screening is required at booking, 16–20 weeks and at 28 weeks gestation. Chronic hypertension (10%) and preeclampsia (12%) are more frequent among diabetic pregnancies. Patients with chronic hypertension and diabetes are at increased risk of intrauterine growth restriction (IUGR), superimposed preeclamptic toxemia (PET), abruptio placentae and maternal stroke. Additionally, problems like urinary tract infection, vaginal candidiasis, respiratory, endometrial and wound infection complicate diabetic pregnancies. Cesarean section rate is increased to about 60%. Since pregnant women are at a greater risk of severe unannounced hypoglycemia, family members should be educated about the use of glucagon injections. Diabetic ketoacidosis (DKA) is rare in pregnancy but is associated with high fetal mortality (20–50%). Precipitating factors for DKA include hyperemesis, infection and tocolytic therapy with beta-sympathomimetics.

Effects of Pregnancy on Diabetes

- Change in eating pattern
- Increase in the insulin dose requirements
- Greater importance to tight glucose control (ideally HbA1c < 6.1%)
- Increased risk of severe hypoglycemia
- Risk of deterioration of pre-existing retinopathy and established nephropathy
- Lower renal threshold for glycosuria.
Effects of Diabetes on Pregnancy

- Need for pregnancy planning
- Risk of congenital malformations, miscarriage, macroadamia, intrauterine disease (IUD), polyhydramnios (5–26%), preterm labor (three fold increase), birth injuries, preeclampsia, infection and increased cesarean section rate
- Need for regular clinical, biochemical and ultrasound monitoring.

Classification of Diabetes

Table 3 shows classification of diabetes.

WHO Criteria to Diagnose Pre-existing Diabetes Mellitus (Non-pregnant Women)

It is difficult to diagnose type 1 and 2 diabetes during pregnancy. Gestational diabetes mellitus (GDM) in early pregnancy is highly suggestive of occult type 2 diabetes. A pregnancy test is recommended in all reproductive age women admitted to hospital for blood sugar management.

One of the criteria shown in Table 4 must be confirmed by repeated testing on a subsequent day unless the patient is symptomatic in which case a single abnormal value will suffice.

Prediabetes

Prediabetics have either impaired fasting glucose (100–125 mg/dL) or impaired glucose tolerance after a 2 hour oral glucose tolerance test (OGTT) (140–199 mg/dL) or both and are at risk of developing diabetes during pregnancy.

Table 3: Classification of diabetes

Diet and Exercise

Women with normal body mass index (BMI) (18.5–24.9 kg/m²) are advised to consume about 30 kcal/kg/day and those with BMI higher than 30%, 24 kcal/kg/day. The diet is composed of 45% carbohydrate, 20% protein and 35% fat, distributed between evenly spaced meals and snacks, according to the patient’s needs. Refined sugars are avoided, high fiber and low fat diet is recommended. Three meals and four snacks are recommended with the last snack being taken at bed time to minimize overnight hypoglycemia and ketosis. Normal pregnant women are prone to ketonuria after 12–16 hours of fasting therefore, monitoring of morning fasting ketonuria helps to guide the level of carbohydrate restriction to avoid the risk of ketonuria.

Walking for 20 minutes two times daily aids in achieving good glycemic control and improves cardiovascular function.

Insulin Therapy

If diet therapy does not achieve good metabolic control as shown in Table 6, then insulin therapy is started. OHA are not used because they cross the placenta and there is a theoretical risk of prolonged neonatal hypoglycemia.

Human insulins are the least antigenic and are the insulin of choice in patients who are started on insulin for the first time. The insulin analog, Lispro is particularly beneficial in women with frequent hypoglycemia as it has a shorter time to peak (1 hour) and thus can be taken at the same time rather than before a meal. It appears to be safe in pregnancy and is proven to be more effective than regular human insulin in reducing fetal macrosomia.

Usually, a regimen with four times daily insulin dosing (nocturnal, intermediate acting insulin and three premeal, injections of fast acting insulin) is recommended. No perfect regime exists for all patients. If delivery is necessary before 34 weeks gestation, steroids are given to enhance fetal lung maturity. Patient is hospitalized for blood sugar control (around 40% increase in dose is suggested) for up to 24 hours after the last steroid dose.

Second Prenatal Visit

Previous blood sugar values and glycosylated hemoglobin/fructosamine values are reviewed especially if there is new evidence of nephropathy or retinopathy. When the HbA1c is high, options include:

- Continuation of the pregnancy and then dealing with any fetal/neonatal problems that arise
- Delaying the decision until 18 weeks of gestation when findings from sonographic survey (Level 1 and 2) and biochemical screening (double and triple test) results are available.

Second Trimester: Biochemical Screening

Risk for neural tube defects is high (10-fold increased over the rate in the nondiabetic population). For this reason, maternal serum, alpha fetoprotein (AFP) screening in the diabetic gravida is mandatory between 16 weeks and 18 weeks of gestation. Since diabetic pregnancies are associated with a lower maternal serum AFP as compared to nondiabetic women adjustment has to be made to allow for the difference in mean AFP levels between diabetic and nondiabetic pregnancies.

Ultrasound

First Trimester

Early dating and viability scan, nuchal translucency, nasal bone and ducts flow evaluation at 11–13 weeks gestation.

Second Trimester

Detailed fetal anatomy survey at 18–20 weeks for anomalies, including detailed assessment of fetal heart.

Third Trimester

Growth scan to access fetal size, every 4–6 weeks, from 26 weeks to 36 weeks in women with overt pre-existing diabetes, once at 36–37 weeks in women with GDM.

Fetal Echo

At 22 weeks if HbA_{1c} is elevated in first trimester.

Third Trimester

The major hazards of this trimester are:

- Intrauterine fetal demise and asphyxia
- Obstetric or medical complications necessitating premature delivery
- Potential fetal-maternal trauma during delivery because of fetal macrosomia
- The decision to deliver depends on the gestational age, maternal condition and fetal status.

Fetal Surveillance

Fetal well-being is assessed by fetal kick count at night, cardiotocographic tracing, umbilical and middle cerebral artery Doppler velocimetry, fetal biometry and amniotic fluid index.
Fetal monitoring should commence at regular intervals from 28 weeks gestation in uncomplicated diabetic pregnancies, however, in patients with IUGR, hypertension, oligohydramnios, preeclampsia, or poorly controlled blood sugars, testing should be started from 26 weeks gestation and must be performed more frequently.

Twice weekly nonstress test (NST) in the 3rd trimester is associated with a lower perinatal mortality rate. A reactive NST is as predictive as fetal biophysical profile score (BPP) shown in Table 7.

### Hospitalization Versus Outpatient Care

Good maternal/fetal outcomes have been achieved with outpatient care. Admission is advised for treatment of preeclampsia, premature rupture of membranes, or premature labor and or if there is poor glycemic control at any time during pregnancy so as to evaluate their diet, adjust insulin and look for potential underlying problems such as infection.

Out patient care is continued until 36 weeks of gestation in patients with good glycemic control, reassuring fetal monitoring tests, no evidence of preeclampsia or hypertension, and normal fetal growth, but are seen twice a week, along with their biweekly NST. Patients who do not meet these criteria are admitted to the hospital for closer maternal/fetal monitoring for the remainder of pregnancy.

### Timing of Delivery

Plan delivery between 38 weeks and 39 weeks gestation in the well-controlled diabetics in the absence of maternal and fetal complications. However, decision to deliver should be based on individual patient. It has been suggested that when insulin requirements suddenly fall, delivery should be considered, as this may be a sign of failing placenta.

### Route of Delivery

Spontaneous vaginal delivery is the aim of modern management. Diabetes by itself is not an indication for cesarean section (LSCS) when the estimated fetal weight is above 4,500 g. Shoulder dystocia remains difficult to predict and there is no conclusive evidence that early induction of labor prevents dystocia.

### Delivery Day and Time

Every effort is made to schedule inductions or cesarean sections as the first thing in the morning. Maintain euglycemia (4-8 mmol/L) during labour. Insulin requirements during induction of labor and elective cesarean section are shown in Flow chart 1. Insulin requirement may fall due to uterine contractions. Intravenous (IV) infusions of short acting insulin via a pump (50 units human actrapid in 50 mL normal saline to produce 1 unit of insulin/mL) and dextrose with potassium (500 mL of 10% dextrose and 20 mmol/l of potassium chloride at a rate of 100 mL/hour) are administered throughout labour via separate IV sets. Potassium is added as insulin drives extracellular potassium into the cells. Maternal capillary blood sugars should be checked every hour with a dextrometer and adjusted according to a sliding scale. Stop insulin if blood glucose is less than 4.0 mmol/l and restart if higher than 7.0 mmol/l. Monitor blood glucose every 15 minutes during second stage of labor.

### Postpartum

As soon as the cord is cut the rate of insulin infusion should be halved. Subcutaneous insulin administration is to be resumed once the women starts eating normally, to either the prepregnancy dose (type 1 diabetes) or 25% lower if she intends to breastfeed.

Continue hourly blood sugar monitoring for 2 hours postdelivery and then postprandially for next 48 hours.

Unrecognized postnatal hypoglycemia may lead to neonatal seizures, coma and brain damage. Therefore, frequent blood checks, early oral feeding or infusion of glucose if oral measures prove insufficient so as to avoid neonatal hypoglycemia.

*Abbreviation: GDM, gestational diabetes mellitus*
Association (ADA-2003). It affects mainly fetal growth rate, but can also cause obesity and slow systemic development of type 2 diabetes. However, there is no increase in the rate of congenital abnormalities.

The perinatal mortality and morbidity are increased in women with untreated GDM.

**Screening for GDM (Flow chart 2)**

Screening is carried out between 26 weeks and 28 weeks gestation, when insulin resistance tends to be at its maximum, but in high-risk women (obese, positive personal or family history of diabetes) it is done in 24–28 weeks.

Clinical characteristics associated with increased risk for GDM are shown in Table 8.

First trimester screening (Table 9) should be performed on patients with risk factors to identify occult type II diabetes. If screening is negative then repeat the screening in the 3rd trimester. The ACOG have suggested that women in the low-risk category could be exempted from universal screening.

The national diabetes data group uses a 50 g oral glucose load followed by a glycemic measure 1 hour later (Table 10). A screening result equal to, or in excess of 140 mg/dL (7.8 mmol/L) is considered abnormal and it is followed by further diagnostic testing with either 100 g OGTT two step or one step 75 g OGTT (Table 11). Both tests are administered after an overnight fast of at least 8 hours but no more than 14 hours and after at least 3 days of unrestricted diet including less than or equal to 150 g of carbohydrate per day. Two or more abnormal values must be measured for the test to be considered positive. Single abnormal value on 3 hour screen if left untreated, are at a high-risk of macrosomia and neonatal morbidity.

**Medical Management**

**Diet and Exercise**

This is the mainstay of treatment. Carbohydrates with a low glycemic index like bran (resulting in sustained slow release of glucose) are advised.

</tbody>
</table>

**Abbreviation:** OGGTT, oral glucose tolerance test

The ADA recommends that normal weight women consume 30–32 kcal/kg in the second half of pregnancy.

**Insulin**

Persistent postprandial hyperglycemia (> 7.5–8.0 mmol/L) or fasting hyperglycemia (> 6.0 mmol/L) despite, compliance with diet is an indication for introduction of insulin therapy. It is usually given as short acting insulin before meals, although in more severe cases intermediate acting insulin at night may be added.

**Oral Hypoglycemic Agents**

Glyburide: This sulphonylurea enhances insulin secretions and does not significantly cross the placenta. It serves as a suitable alternative to insulin for the treatment of GDM with similar perinatal outcomes.

However, it should not be used in the 1st trimester and has the disadvantage that it sometimes takes more than 1 week to observe the effects of dose titrations.

**Metformin:** In women with polycystic ovary syndrome (PCOS), metformin may be safe and may reduce the risk of
miscarriage and the development of GDM when used for the entire pregnancy.\textsuperscript{11}

**Obstetric Management**

**Antepartum**

Gestational diabetes mellitus is associated with an increased risk of PET and thus women should have regular checks of blood pressure and urine analysis. Regular ultrasound assessment for fetal growth is advisable as this is likely to impact decision regarding insulin therapy and mode and timing of delivery.

Each case should be assessed individually regarding the timing of delivery. However, most obstetricians tend to deliver well-controlled GDM around 39–40 weeks. Emphasis must be laid on two things:

- Avoiding shoulder dystocia
- Glycemic management.

**Intrapartum**

Women on small doses of insulin (< 20 units/day) may be managed without insulin during delivery, as women do not eat much during labor. However, women on larger doses are managed with an insulin sliding scale.

**Postpartum**

The ADA recommends 75 g. OGTT at 6 weeks postpartum and annual FBS to exclude impaired glucose tolerance or diabetes outside pregnancy. Risk of recurrence (33–50% chance of GDM in future pregnancy) should also be explained to the women.\textsuperscript{12}

**Breastfeeding**

Breastfed infants have a much lower risk of developing diabetes. Lactation has beneficial effect on the overall maternal glucose and lipid metabolism.

**Prevention**

Loss of weight prior to pregnancy following appropriate diet and lifestyle modifications and regular exercise result in reduction in the risk of development of type 2 diabetes mellitus, and GDM in some patients but not in very susceptible individuals.

**Medicolegal Pitfalls**

Occurrence of a severe, debilitating congenital anomaly in the infant of a mother with diabetes.

The clinician, when discussing pregnancy plans with a woman with pre-existing diabetes, must mention the preventability of these birth defects with good glycemic control prior to pregnancy and this counselling should be recorded in the patient’s medical record.

Risk of perinatal asphyxia, birth injury (clavicle or humerus fractures, brachial plexus disruption, or less commonly, direct cerebral or cervical spine trauma) permanent palsy of the arm and hand after a difficult delivery of an obese fetus usually leads to litigation. Clinicians managing these patients must obtain an ultrasound based estimation of fetal weight in the last 2–3 weeks prior to delivery and offer cesarean delivery to a patient with an estimated fetal weight of more than 4,500 g and if the labor is prolonged and patient is unable to expel the fetal head spontaneously after 2–3 hours of pushing effort.

**CONCLUSION**

Improved medical and obstetric management of diabetes has resulted in good maternal and neonatal outcomes; however, major challenges remain in preventing congenital anomalies and macrosomia. The solution lies in maintaining metabolic milieu of the diabetic gravida as close as possible to normal with multidisciplinary support.

**REFERENCES**

INTRODUCTION
Knowledge of liver function and its role in various disease processes is essential for the practicing obstetrician. Though severe liver disease is only an occasional complication during pregnancy, it has disproportionately high mortality rates. This chapter focuses on conditions which are specific to pregnancy [acute fatty liver, cholestasis, hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome] and those which are commonly seen in pregnant women (viral hepatitis, gallstones).

ETIOPATHOLOGY
In normal pregnancy, with adequate nutrition, the metabolic changes seem to be without significant effect on hepatic function. Pregnancy can produce some clinical manifestations which are typical of liver diseases. Itching is seen in later pregnancy due to the effect of accumulated bile acids under hormonal effects on the biliary system. Abnormalities on liver function testing suggest primary hepatic disease or complication involving the liver and need to be completely evaluated. A summary of the liver function tests in pregnancy is presented in Table 1.2 In general, levels of bilirubin and transaminases are specific guides to liver dysfunction. They are never altered as a result of normal changes of pregnancy.

Hepatic diseases of various etiologies and varying severity can occur in pregnancy. They have a differential impact on pregnancy. Maternal, and subsequently the perinatal outcome are affected by the etiology, severity and gestational age of occurrence of the hepatic dysfunction. There are a number of disorders specific for the pregnant woman, which are not seen at any other time in life and they command the attention of the obstetrician. The spectrum of liver diseases can be divided into pregnancy-specific and pregnancy-associated. Some examples of these conditions are presented in Table 2. Diseases from both groups can be severe enough to cause hepatic failure (Flow chart 1).

VIRAL HEPATITIS
Hepatitis is the most common serious liver disease encountered in pregnant women. The mode of transmission, etiopathology and clinical picture is not altered in pregnancy in most women. Most cases of viral hepatitis are self-limiting. About 10% of women infected with hepatitis B virus will become carriers. There is a high-risk of vertical transmission of the hepatitis B virus to the neonate to the tune of 95% when the mother is HBsAg and HBeAg positive. About 1% of cases with viral hepatitis develop fulminant hepatic necrosis. The usual presentation in this case is hepatic encephalopathy and mortality is as high as 80% in these patients. The course of hepatitis E virus infection is altered by the pregnant state. The case fatality rate amongst pregnant women was up to 12 times that for nonpregnant females and males. The risk of fulminant hepatic failure is about 15% and mortality is 5%.3 This infection is also more common than what it was thought to be earlier.

ACUTE FATTY LIVER OF PREGNANCY
Acute fatty liver of pregnancy (AFLP) is a rare disorder characterized pathologically by microvesicular steatosis on liver histology. The pathology resembles that seen in Reye’s syndrome. It usually appears in the third trimester. The reported incidence is 1 in 10,000 pregnancies. However, modern reports suggest that milder varieties of the syndrome may be more common and not universally fatal.4 The etiology

Flow chart 1: Evaluation of cholestasis during pregnancy

Abbreviation: RUQ, right upper quadrant

The syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP) is considered to be a complication or a variant of severe preeclampsia-eclampsia. There is considerable debate regarding the definition, diagnosis, incidence, etiopathology and management of this syndrome. The name was coined by Weinstein in 1982. The criteria for diagnosis have varied with different reports. A standard definition utilized by most studies, however, is given by Sibai as follows:

- Hemolysis—microangiopathic hemolytic anemia characterized by burr cells, increased bilirubin (> 1.2 mg/dL), and increased lactic dehydrogenase (> 600 IU/L).
• Elevated liver enzymes—increased SGOT (> 72 IU/L), and increased lactic dehydrogenase as above.
• Low platelets—platelet count less than 100,000 per mm³.

**CLINICAL PRESENTATION,**
**INVESTIGATION AND DIFFERENTIAL DIAGNOSIS**

Jaundice may be of varying severity and presentation. The timing of the onset may be a clue to the etiology. Viral hepatitis may occur in any trimester or the puerperium. Hyperemesis is generally seen in the first trimester, whereas HELLP syndrome and AFLP occur in the late second or third trimester. The highlights of the differential diagnosis of these three important conditions are presented in Table 3 and Flow chart 2.®

With reference to hepatitis B, screening should be offered as a routine to all pregnant women. If they are found to be carriers, the infectivity should be evaluated by assessing the antigen status.

**Abbreviations:** HELLP, hemolysis, elevated liver enzymes, and low platelets; SGOT, serum glutamic oxaloacetic transaminase; DIC, disseminated intravascular coagulopathy
Recommended serologic tests are: hepatitis A IgM, hepatitis B surface antigen and hepatitis B core antibody, hepatitis C antibodies, cytomegalovirus IgM, herpes simplex virus IgM and Epstein-Barr virus IgM.

**MANAGEMENT**

Jaundice is usually managed supportively and conservatively in pregnancy as in the nonpregnant state. The mainstay of therapy is hydration, avoidance of fatty and high protein diets, maintaining normoglycemia and vitamin supplementation. When there is hepatic failure, measures to minimize the mortality from encephalopathy are initiated such as low protein diet, high bowel enemas and lactobacillus supplementation. The management points of special interest in pregnancy are discussed with the specific condition.

**Viral Hepatitis**

Human serum immunoglobulins against the hepatitis A and B virus are available. If administered early in the disease process, they may reduce morbidity. This may be relevant for women who already have compromised liver or immune function.

In the carrier state, hepatitis B does not seem to have any additional risks for pregnancy. Delivery should be as atraumatic as possible to minimize vertical transmission risk. Fetal scalp blood sampling, scalp electrodes and ventouse delivery may be avoided in these cases. There is no indication for an elective cesarean section to prevent vertical transmission of hepatitis B. Risk of transmission to the neonate is minimized by administration of hepatitis B immunoglobulin in the first 24 hours of life. Active immunization with hepatitis B vaccine should be initiated simultaneously. Breastfeeding is not contraindicated provided the babies are immunized.

**Acute Fatty Liver of Pregnancy**

The pathophysiological derangements should be corrected as rapidly as possible while embarking on the chosen plan for delivery. There is no role for conservative management for this condition. Intensive care support is required. Correction of coagulopathy and preventing hypoglycemia are established modalities of treatment. Cesarean delivery does not seem to improve the outcome and vaginal birth would be in the best interests of the mother, keeping in view the high-risk of anesthesia and surgery in these patients.

**HELLP Syndrome**

Management of patients with HELLP syndrome includes the same principles as that of severe preeclampsia-eclampsia. A rapid assessment and liberal use of blood products to correct coagulation abnormalities is central to the management. Fetal status should be evaluated. The combination of maternal and fetal status should be considered in order to decide the timing and mode of delivery. Newer developments include the use of high dose steroid therapy. Magann et al. have showed significant improvement in the laboratory and clinical parameters associated with HELLP syndrome in women who received high-dose antenatal corticosteroids. This is one of the therapeutic modalities, which is feasible as compared to the use of the other proposed therapies such as use of antithrombin and plasmapheresis. Further work needs to be done in this area to clarify the precise role, dose and results with high-dose steroid therapy. The reversal of the pathological features and improvement in maternal condition is ultimately achieved only by delivery. Recovery of laboratory abnormalities usually is within 60 hours from delivery. However, these patients need to be followed up after delivery with serial laboratory assessment to rule out deteriorating maternal parameters. An important aspect to be considered is the risk of recurrence. An extensive study by Sullivan et al. found the risk of recurrence of the HELLP syndrome to be 19–27%. A large number of patients in a developing country being illiterate, may fail to grasp the magnitude of the disease they have survived. Educating the patient to be especially cautious with all future obstetric events and inform the next caregiver about earlier complications is a vital part of the management.

**REFERENCES**

INTRODUCTION

Malaria is an endemic disease in many parts of Asia, Africa, Oceania, Central and South America. Worldwide it is a major health concern. About 300–500 million infections and approximately 1.1–2.7 million deaths in each year are caused by malaria. World Health Organization (WHO) (Table 1). Malaria has been eradicated from North America, Europe and Russia. Though resurgence is observed predominantly in the tropical countries, it is a persistent threat to the non-malarious countries, because of transmission across the international borders and travelers.

Malaria is a protozoal disease caused by the bite of an infected female Anopheles mosquito (Figs 1A and B), four species of plasmodium (P. vivax, P. falciparum, P. malariae and P. ovale) are the infective agents. Malaria through blood transfusion is not uncommon. Incubation period is usually short in that case.

EPIDEMIOLOGY OF MALARIA COMPLEX

Plasmodium vivax and P. falciparum are the causative agents in South-East Asian Region (SEAR). Deaths from malaria are mainly due to P. falciparum. P. falciparum infection predominates in Africa, New Guinea and Haiti. P. vivax is more common in central America and Indian subcontinents. Infection with P. malariae is observed in sub-Saharan Africa.
Infection with *P. ovale* is rare (<1%). *P. falciparum* infection is on the rise. Transmission of malaria is mainly by female *Anopheles* mosquitoes. However, infection may sometimes occur through blood transfusion (vertical transmission) which is rare. Transmission by needlestick injury has been recorded in a few cases. In India during the year 2000-01, there is resurgence of malaria in the states like Orissa, Meghalaya, Mizoram, Assam, Tripura, Andhra Pradesh and Chhattisgarh. Increase in the proportion of *P. falciparum* infection (80–85%) has been observed in the SEAR. During the year 2000-01, slide positivity rate (SPR), in India ranged from 0% to 17% (Fig. 2) depending upon the region. State-wise infection percentage rate with *P. falciparum* in the year 2000 and 2001 revealed significant rise in the Eastern States (Orissa, Bihar), North-Eastern States (Meghalaya, Tripura, Assam, Mizoram, Manipur, Sikkim), Western State (Maharashtra), Southern State (Andhra Pradesh) and Central States (Madhya Pradesh, Chhattisgarh) compared to the others (Fig. 3).

Percentage distribution of death from malaria during the years 1997, 2000 and 2001 revealed significant fall in the majority of the states except the North-Eastern States (Fig. 4).

The development of drug resistance has further intensified the problem. Vector resistance, inadequate control programs are the other factors for the resurgence.

Endemicity of malarial infection depends on parasite density. Areas may be defined as hypoendemic, meso-endemic, hyperendemic or holoendemic when the parasitemia rate is 10%, 11–50%, 51–75% or more than 75%, respectively.

### PATHOLOGY

The infected erythrocytes become irregular, rigid and antigenic. The hemoglobin (Hb) is consumed and degraded by the growing parasite. The red cell membrane becomes sticky due to an adhesive protein. This phenomenon of cytoadherence and resetting is significant in *P. falciparum* infection. This results in sequestration of red cells in vital organs where this interferes the microcirculation and metabolism. Immunity is impaired during the second and third trimesters of pregnancy. This results in high infection rate. Due to the same reason severity of infections and complications are more.

Spleen removes both the parasitized and uninfected red cells by immunologic and filtrative function.

### Immunology

The mechanism of complex cellular and humoral immunity is not clearly understood. Immunoglobulin G (IgG) antibody is protective. Both humoral and cell-mediated immunities are developed with plasmodial infection. Unfortunately such
**Fig. 3:** Statewise *Plasmodium falciparum* percentage (PF%) in 2000 and 2001

**Fig. 4:** Percentage distribution of death from malaria during 1997, 2000 and 2001
immunity lasts for only a short period. Passively transferred IgG from mother to neonate confers relative protection against malaria in the first few months of life. Primiparous women are more susceptible to infections than the multiparous, especially with *P. falciparum* malaria. Placental parasitemia is common (20–60%). But congenital malaria occurs which is less than 5% of newborns.

Maternal intravenous (IV) infection and/or tuberculosis, cause intense parasitization of the placenta with sequestration of parasitized erythrocytes in the placental circulation. High parasite density increases the risk of congenital malaria.

**Diagnosis**

The typical paroxysms of fever occur every 48 hours for *P. vivax* and *P. ovale*, every 36–48 hours for *P. falciparum* and every 72 hours for *P. malariae*. Fever is due to release of Hb, merozoites, malaria pigments, toxic cellular debris and various cytokines. Demonstration of asexual forms of the parasite in the peripheral blood smears (thick and thin film) by Romanovsky staining is diagnostic. Both the parasites and a minimum of 200 white cells should be counted. Card tests for the detection of specific antibody have been introduced currently. Fluorescent microscopy, polymerase chain reaction (PCR)-based detection of *plasmodium* deoxyribonucleic acid (DNA) in the blood are also being used. Unfortunately negative blood film does not rule out malaria infection.

**Effects of Malaria on Pregnancy**

In hyperendemic (51–75%) and holoendemic (> 75%) areas, pregnancy complications are increased specially with *P. falciparum* malaria. Complications involve both the mother and the fetus. *Maternal complications* are high due to increased severity of the disease as compared to a nonpregnant state. *Maternal morbidity and mortality* are directly related to the degree of vital organ dysfunction and the proportion of infected erythrocytes. Mortality rises significantly when 3% or more erythrocytes are infected.

**IMPORTANT MATERNAL AND FETAL COMPLICATIONS**

Pregnancy complications are directly related to the type and degree of parasitemia. Infection in early months often ends in miscarriage. Preterm labor and prematurity are well-known complications.

Low birthweight baby is seen more specially when mother suffers from anemia and other complications. Severe parasitization may even cause fetal death. Maternal human immunodeficiency virus (HIV) and/or tuberculosis predisposes to higher rate of fetal complications. At times mother may remain asymptomatic due to sequestration of parasitized erythrocytes in the placental microcirculation. Fetal growth restriction is more with falciparum infection as compared to vivax. During labor, fetal distress is often observed.

Diagnosis of congenital and neonatal malaria is often difficult. Clinical manifestations are rare before 3 weeks. Maternal antibodies offer protection to the neonate, and may delay the onset of clinical manifestations and diagnosis. The major maternal complications are:

- **Anemia and other hematological changes:** Anemia is the major maternal complication in pregnancy. Anemia is usually normochromic and normocytic type. It is due to accelerated red cell destruction, and also removal by spleen. There is associated ineffective erythropoiesis due to bone marrow suppression. Drug resistant cases develop severe anemia due to repeated or continued infection. There is thrombocytopenia and reduced antithrombin III level. Blood coagulation parameters are altered specially in severe cases.

- **Hypoglycemia:** It is a significant problem in pregnant women. It is due to increased glucose consumption both by the host and the parasite. There is also decreased hepatic gluconeogenesis and increased pancreatic insulin secretion by the drugs used (quinine). Hypoglycemia (plasma glucose < 40 mg/dL) is a poor prognostic indicator.

- **Metabolic acidosis (lactic acidemia):** It is due to anaerobic glycolysis. It is often associated with hypoglycemia. Arterial pH less than 7.25 with venous lactate level greater than 15 mmol/L indicates severe metabolic abnormality.

- **Convulsions and/or coma:** They are commonly observed in cerebral malaria. Falciparum malaria carries a high mortality rate (20%), unless promptly detected and treated. Associated complications like hypoglycemia, severe anemia, encephalopathy worsen the outcome.

- **Pulmonary edema and acute respiratory distress syndrome:** They are observed specially with falciparum malaria. However, it may be observed in cases with vivax malaria also. Ethiopathogenesis of such noncardiogenic pulmonary edema is not well-understood. Decreased pulmonary compliance, severe hypoxemia is associated with diffuse pulmonary infiltrates on chest radiograph. Reduction in surfactant synthesis due to damage of type II pneumocytes and alveolar protein exudates are the important patholoogy. The patient needs mechanical ventilatory support besides the treatment of malaria.

- **Renal failure:** It is due to block of renal microcirculation by sequestrated erythrocytes. This is common with severe falciparum infection. Acute tubular necrosis is the pathology. Cortical necrosis is not observed. Renal failure is associated with high maternal mortality. Early diagnosis and dialysis improves the outcome.

- **Jaundice (hepatic dysfunction):** Mild jaundice is common due to hemolysis. Jaundice may be severe with falciparum infection. Excessive hemolysis, hepatic cell damage and
choleretic agents. Choleretic agents increase the bile flow, thereby promoting the elimination of bilirubin and biliverdin. They are used to treat obstructive jaundice, where biliary flow is impaired due to obstruction of the biliary ducts.

- **Others**: Other types of choleretic agents include the bile acid sequestrants, which bind bile acids in the gastrointestinal tract and reduce their absorption, thereby increasing their excretion in the feces. Examples include cholestyramine and colestipol.

In the context of malaria, the treatment and prevention strategies are crucial.SECTION

**EFFECTS OF PREGNANCY ON MALARIA**

- Risk of infection is high due to immunocompromised state.
- Frequency of infection is high, especially in the second or third trimester.
- Severity of infection is high, especially in primigravida.
- Complications are high.

**MANAGEMENT**

**Prevention** is directed for improvement of sanitation and initiation of control programs with infrastructure. Personal protection is obtained with the use of repellants and bed nets. Strategies have been adopted by WHO, United Nations Children’s Fund (UNICEF), United Nations Development Programme (UNDP), World Bank, Government of India (1998) against malarial infection. These include:

- Intensity of malaria control activities in “high-risk areas”
- Early case detection and treatment
- Personal protection and community participation
- Vector control.
- High-risk area is defined where:
  - Slide positivity
  - Slide falciparum rate is 30% with SPR of 3%
  - Area with chloroquine-resistant falciparum infection.

Revised strategy subsequently has been recommended by WHO (2000). These include:

- Presumptive diagnosis of malaria and to institute treatment
- Radical treatment of malaria
- Mass chemoprophylaxis where annual parasite index (API) is more than 5
- To institute antenatal chemoprophylaxis
- Consideration of multidrug therapy for patients with HIV/acquired immunodeficiency syndrome (AIDS) and/or tuberculosis to minimize drug resistance.

Mass chemoprophylaxis in children and in pregnant women is not recommended universally. There are several reasons from this. It is not possible to achieve complete suppression of infection. Secondly, it interferes with the development of immunological defense of the individual. Lastly, it causes development of drug resistance. Drug hazards are not uncommon when used on a long-term basis, especially during pregnancy. These strengthen the importance of personal protection.

**Chemoprophylaxis**: Pregnant women residing or traveling in endemic (malarious) areas should receive prophylaxis with chloroquine or proguanil. Chloroquine (300 mg base) is given orally once a week. This is considered safe and is well-tolerated in pregnancy. Proguanil 200 mg/day is also used as an alternative. Folic acid 5 mg/day should be given when proguanil is used.

Mefloquine (15 mg/kg as single dose) is being used in many countries as it is found effective against multidrug-resistant falciparum malaria. It is reasonably well-tolerated. But its safety in pregnancy is yet to be determined. Studies in Africa mefloquine prophylaxis found effective and safe during pregnancy. One study from Thailand revealed its use was associated with an increased risk of stillbirth. The manufacturer advises that prophylaxis with mefloquine should be avoided. Though most of the studies in pregnancy including its use in the first trimester revealed no evidence of harm.

Travelers should start antimalarial drug at least 1 week before departure to achieve the desired therapeutic antimalarial blood concentration. The chemoprophylaxis should continue for another 4 weeks after leaving the endemic area.

In sub-Saharan Africa, severe anemia in pregnancy due to malaria is common. A trial in Kenya showed intermittent treatment with sulfadoxine-pyrimethamine during pregnancy reduced the severe anemia by nearly 40% and halved the incidence of low birthweight.

**TREATMENT**

Not all the antimalarial drugs are safe in pregnancy. Drug selection depends upon the severity of infection (parasite density) and the drug sensitivity of the parasite. Parenteral antimalarial therapy is needed in a case with severe and/or complicated malaria. Because of resistance, chloroquine may not be effective. Drugs and dosage of commonly used antimalarials in pregnancy are given in Table 2.

Drugs not used (contraindicated) or used with limited experience in pregnancy are: doxycycline, artemisinin (artemether, artesunate), pyrimethamine, halofantrine, atovaquone, maloprim and mefloquine. Proguanil with atovaquone: Proguanil with atovaquone are recommended for treatment of falciparum malaria when other antimalarial drugs are found resistant. For the use in pregnancy, no information is available. Manufacturer’s advice is to avoid unless potential benefits outweigh the risks.

For eradication therapy, primaquine is the recommended drug. But it is contraindicated in pregnancy and in glucose-6-phosphate dehydrogenase deficiency.

Patients with severe anemia in pregnancy need blood transfusion. Those with hematocrit less than 20 should be given packed cell transfusion or exchange transfusion. Folic acid supplementation should be continued. Associated complications should be managed appropriately with careful monitoring of the patient. Intensive care monitoring is needed for patients with acute respiratory distress syndrome.
Malaria in Pregnancy

131

(ARDS), renal failure, metabolic acidosis of hepatic dysfunction.

Hyperpyrexia needs immediate care with ice sponging, antipyretic (paracetamol), specific drug therapy and maintenance of fluid balance. Fluid balance and blood glucose should be monitored at a regular interval. Convulsions should be aggressively treated. Lumbar puncture and examination of the cerebrospinal fluid should be done when the patient remain unconscious for a prolonged period.

Poor Prognostic Indicators

Clinical Features

Features of severe falciparum malaria

Laboratory Findings

- Hyperparasitemia level (> 5%)
- Severe anemia (Hb < 7 gm/dL)
- Hypoglycemia (< 40 mg/dL)
- Acute respiratory distress
- Elevated total bilirubin (> 50 mmol/L)
- Acidosis (arterial pH < 7.3)
- Raised serum creatinine (> 265 mmol/L)

Immunology, host response and vaccines: Pregnancy is not a state of immunodeficiency, but is a state of altered immune function. The major changes observed are a modulation away from cell-mediated immunity to humoral or antibody-mediated immunity. T helper 1 cells and natural killer cells decline whereas T helper 2 cells increase. Clinically the decrease in cellular immunity leads to the increased susceptibility to intracellular pathogens like malaria.

Both humoral (IgG, IgM and IgA) and cellular immunity can protect malarial infection. But mechanism is not well-understood. Genetic disorders (Hb A/S) confer protection because of low oxygen tension. Antibodies to parasitic antigens prevent parasitic multiplication. The protein PEMPI is an important antigen of falciparum malaria. Unfortunately parasite-strain diversity, lack of correlation between level of antibodies and clinical response made the progress of vaccine development slow.

Thrombophilia in Pregnancy

INTRODUCTION

Hemostatic Changes in Pregnancy (Table 1)

During pregnancy, there is a marked increase in the procoagulant activity and concomitant decrease in anticoagulant activity.

Pregnancy itself can be considered as an acquired thrombophilic state. Even though procoagulant activity is increased during pregnancy, very efficient balance is maintained between clot formation and clot breakdown. Pregnant woman is 4–10 times more prone to develop intravascular thrombosis as compared to nonpregnant, in presence of some triggering factors such as:

- Immobilization after a major surgery
- Obesity
- Presence of congenital or acquired thrombophilias.

THROMBOPHILIA

Thrombophilias refers to disorders which are associated with persistent hypercoagulable state and a tendency towards thrombosis. Thrombophilia is of two types:

1. Inherited thrombophilia
2. Acquired thrombophilia

Most thrombophilias are inherited, though some can develop later in life.

Risk Factors for Thrombosis

They can be acquired or inherited.

Inherited Risk Factors

The inherited causes for thrombosis are enumerated in Table 2.

Acquired Risk Factors

- Antiphospholipid syndrome
- Hyperhomocysteinemia due to B₁₂, B₆, or folate deficiency.

Etiopathogenesis

Of the different risk factors, in the inherited group the most common are:

- Factor V Leiden: Incidence of 5.9%
- Prothrombin mutation: Incidence of 2.3%

Both are inherited in an autosomal dominant pattern, meaning that an affected person needs to inherit the gene

</tbody>
</table>

Table 2: Inherited causes for thrombosis

- Factor V Leiden
- Protein C deficiency
- Protein S deficiency
- Activated protein C resistance (APCR)
- Antithrombin deficiency
- Prothrombin 20210 mutation (elevated prothrombin level)
- Hyperhomocysteinemia [cytosine 677 thiamine (C-677T) methyl-ene tetrahydrofolate reductase (MTHFR) mutation]
from only one parent. Each child of an affected parent has a 50% chance of inheriting the thrombophilia.

Factor V Leiden: Heterozygosity for factor V Leiden mutation is responsible for venous thromboembolism in about 20–30% of women. When guanine is substituted for adenine at position 506 in factor V polypeptide then it is called as factor V Leiden. Resistance to activated protein C (APC) caused by factor V Leiden is responsible for increased risk of venous thrombosis.1,2

Prothrombin mutation: Recently described guanine 20210 adenine (G20210A) mutation in prothrombin is associated with higher plasma prothrombin concentrations and increased risk for venous thromboembolism.3

Hyperhomocysteinemia: It could be inherited or acquired. Mutation in MTHFR (C-677T) results in decreased synthesis of 5-methyltetrahydrofolate, which is primary methyl (CH₃) donor in conversion of homocysteine to methionine. On account of this homocysteine concentration is increased, which is a risk factor for thrombosis.4 About 3% of patients with intravascular thrombosis may have deficiency of protein S, protein C and antithrombin.5

MECHANISM OF CLOTTING DISORDERS DUE TO INHERITED DEFECTS

Antithrombin Deficiency

Antithrombin III deficiency is a heterogeneous disorder inherited in an autosomal dominant mode.

Antithrombin III is a naturally occurring anticoagulant. It is a serine protease inhibitor. It is a major physiological inhibitor of thrombin and factor IXa, Xa, Xla and XIIa. Its deficiency is responsible for increase in fibrin formation. In 70% of women, it causes vascular thrombosis during pregnancy or puerperium.

The frequency of symptomatic antithrombin deficiency in general population has been estimated to be 1:600 to 1:5,000. In all women with vascular thromboembolism (VTE), antithrombin III deficiency is detected in about 1%.6

Preston et al. in 1996 reported the highest risk of miscarriage and 5.2-fold increase in stillbirth rate in cases with antithrombin III deficiency.

Protein C Deficiency

Protein C is naturally occurring anticoagulant which gets activated by conversion to an active serine protease called APC.

In presence of protein S, it can inactivate factors V and VIII.

Prevalence of protein C deficiency in general population is 1 : 200 to 1 : 300 (Flow chart 1).

Data from European Prospective Cohort on Thrombophilia (EPCOT) study showed the modest increase in the risk of stillbirth among women with protein C and protein S deficiencies. There is not much difference in the risk of abortions as compared to control group.

Activated Protein C Resistance (Factor V Leiden)

Activated protein C deficiency was described in year 1993. In some cases production of APC is adequate, but due to presence of factor V Leiden, there is resistance to its anticoagulant effect.

Factor V Leiden mutation is frequent in 3–7% of healthy white population but it appears to be far less prevalent or even nonexistent in Asian population. In various studies, APCR was found in a wide range (10–64%) of patients with venous thromboembolism. There are controversial reports regarding the increased risk of recur rent fetal loss in pregnant women with factor V Leiden mutation. The EPCOT study revealed hardly any change in the risk of abortions and stillbirth. Study carried out by Rai et al. and Grandone et al.7,8 revealed significant increase in prevalence of recurrent pregnancy loss. In a nonpregnant population, 90–95% cases of APCR are associated with factor V Leiden mutation. Rest of the 5% can be attributed to more recently described mutation—factor V Cambridge mutation. This is the mutation occurring at 306 APC cleavage site. During pregnancy, resistance to APC increases as pregnancy advances.

Prothrombin Gene Mutation

The substitution of guanine for adenine at nucleotide 20210 of the prothrombin gene has been associated with elevated plasma levels of prothrombin and increased risk of venous thrombosis. Prothrombin gene mutation is found in 2% of the population worldwide. This risk is the second common genetic factor for venous thrombosis in certain white population. In 6–18% of patients with venous thromboembolism, prothrombin gene mutation is the causative factor.9

Protein S Deficiency

It goes hand in hand with APC deficiency causing loss of fibrin generation. Its prevalence among patients of venous thromboembolism is about 1–2%.
Hyperhomocysteinemia

Homocysteine is derived from dietary methionine and its plasma level during pregnancy is very low. In non-gravid stage, it is 5–15 µmol/L. Hyperhomocysteinemia causes:
- Increased production of reactive oxygen species (ROS) with increase lipid peroxidation.
- Glutathione peroxidase enzyme activity is suppressed; thus, detoxification of lipid peroxide cannot be adequate.
- It suppresses nitric oxide (NO) production by endothelial cells by stimulating increased production of asymmetric dimethyl arginine.
- It increases concentration of free oxygen radicals, thus decreasing the bioavailability of NO.
Due to these effects, there is vasoconstriction and intravascular thrombosis.10

Postimplantation Effect
- There is accumulation of lipid-laden macrophages in the intima of spiral and decidual arteries along with fibroblastic proliferation and fibrinoid necrosis of the media, causing uteroplacental insufficiency.
- Recent studies have suggested that APLA may reduce annexin V on the surface of placental villi which have antithrombotic factor.13 Reduction of annexin V promotes thrombosis in the intervillous space leading to placental insufficiency. Elevated levels of APLA are associated with recurrent abortions,14,15 as well as pregnancy-induced hypertension (PIH), intrauterine growth restriction (IUGR), intrauterine death (IUD) and abruptio placentae. However other investigators such as Simpson et al. recently challenged the role of APLA as main causative factor in abortion.16,17
The risk of thrombosis in otherwise healthy individuals with APLA appears to be very low. As per the APLA titer women are classified as:
- Negative: Less than 10 immunoglobulin G phospholipid units (GPL) units
- Low positive: 10–20 GPL units
- Moderate positive: 20–100 GPL units
- Strong positive: Greater than 100 GPL units.

Hyperhomocysteinemia

This could be acquired due to dietary deficiency of B₁₂, B₆, folic acid which act as cofactors in the conversion of homocysteine to methionine.
There are clinical and experimental evidences suggestive of an association between hyperhomocysteinemia and arterial thrombosis.

Placental Pathology Associated with Thrombophilias and Pregnancy Complications

In normal pregnancy, there is high volume and low pressure intervillous blood flow. This is because of trophoblastic invasion in spiral and radial arteries replacing intima and media. This is regulated to some extent by the balance between plasminogen activators and inactivators.
Even though pregnancy is a hypercoagulable state, thrombosis in the intervillous space is prevented by anticoagulants such as protein S, protein C and surface annexin V due to which placental perfusion is maintained.
Due to activation of coagulation cascade (Flow chart 2), fibrin deposition has been seen on the chorionic villi. Endothelial cells in these areas appear to be deficient in the production of anticoagulant factor such as plasminogen activator inhibitor type 1 (PAI-1), causing intravascular microthrombi and placental infarcts.

ACQUIRED THROMBOPHILIA

The most common causes of acquired thrombophilia, which have adverse effect on pregnancy, are:
- Antiphospholipid antibody (APLA) syndrome
- Acquired hyperhomocysteinemia

Antiphospholipid Antibody Syndrome

Antiphospholipid antibodies are heterogeneous group of antibodies directed against negatively charged phospholipids. The most common antibodies are anticardiolipin antibodies, lupus anticoagulant, antibodies to phosphatidylserine, etc. Relation between APLA and recurrent pregnancy loss has been recognized for the past 2 decades. It is the most acceptable and treatable cause of recurrent pregnancy loss.

Action on Endothelium

Antiphospholipid antibodies generate hypercoagulable state by activating endothelial cells for production of endothelial cell adhesion molecule 1 (ECAM-1)/vascular cell adhesion molecule 1 (VCAM-1). Due to its glue-like action, aggregations of the platelets occur. So the production of thromboxane A₂ (TXA₂) is increased thus leading to vasoconstriction and intravascular thrombosis. It also inhibits the production and impairs fibrinolytic response of protein C, protein S and antithrombin III.

Implantation Loss

Cytotrophoblastic cells express phosphatidylserine on their surface. Antibodies against it prevent differentiation of syncytiotrophoblast and cytrophoblast along with cell injury and death of the embryo.
Many et al.\textsuperscript{18} carried out study on placental findings in women who had thrombophilia and severe pregnancy complications with a group of women having pregnancy complications without thrombophilia. In the first group, large number of placentae showed villous infarcts, fibrinoid necrosis as compared to second group. However, reports of Mousa et al.\textsuperscript{19} quoted no such difference in very similar designed study.

Arias et al.\textsuperscript{20} evaluated 13 women with obstetric complications having thrombotic lesions of the placenta. In 10 out of 13 women (77\%) inherited thrombophilias was detected.

**CLINICAL PRESENTATION**

**Thrombophilia Associated Pregnancy Wastage**

Successful outcome of pregnancy is dependent on the development of adequate placental circulation. Intervillous or spiral artery thrombosis and inadequate placental perfusion due to inherited or acquired thrombophilia may result in various gestational pathologies (Table 3) such as:

- Implantation failure
- Abortions
- Preeclampsia with early onset

- Intrauterine growth restriction
- Intrauterine death
- Abruptio placentae
- Vascular thromboembolism
- Deep vein thrombosis (DVT)

The frequent pathological findings of infarction and utero placenta thrombosis in placentae from pregnancy complicated by fetal growth restriction (FGR), fetal loss, abruptio placentae, preeclampsia suggest strong relationship between inherited thrombophilia and pregnancy complications. Majority of the complications are because of abnormal placental vasculature.\textsuperscript{21-23}

Dekker et al.\textsuperscript{24} tested women with severe preeclampsia for presence of inherited and acquired thrombophilias. A high
rate of protein S deficiency, APC, hyperhomocysteinemia and antiodioplin antibodies was found.

Dizon-Townson et al.25 and Nagy et al.26 described higher prevalence of factor V Leiden mutation in women with severe preecclampsia as compared to the control. Rajkovic et al.27 reported that homocysteine levels were doubled in 20 women with preecclampsia as compared to normotensive women (n=19).

Recent meta-analysis28 suggested association of factor V Leiden mutation, hyperhomocysteinemia, deficiency of protein S, protein C and antithrombin III only with severe preecclampsia. The association between placental abruption and thrombophilia has been demonstrated in several studies. Alfrevic et al.29 found that there was significant relationship between placental abruption and factor V Leiden mutation.

European prospective cohort on thrombophilia study report revealed that the risk of fetal loss was 1.3 times greater in women with thrombophilia than in a woman without thrombophilia.

De Vries et al.30 studied 62 women with thrombophilia. Of them 31 women had abruptio placentae, 18 had intrauterine growth restriction and fetal demise (IUFD), 13 had IUFD. Of the 13 cases of IUFD, hyperhomocysteinemia was present in 38%, protein S deficiency in 23% and factor V Leiden mutation in 12.5%.

Several studies have reported that early fetal loss in women with APL syndrome is in the range of 50–70%. Of all inherited thrombophilias, many reports find high prevalence of factor V Leiden mutations and recurrent fetal loss.

Methylenetetrahydrofolate reductase or prothrombin mutations were not very common in women with fetal loss.

**Congenital Thrombophilia and Maternal Venous Thromboembolism**

Risk of VTE in pregnancy is approximately 6 times greater than in nonpregnant women. It is a major cause of death among women during pregnancy and puerperium.

Recently, Gerhardt et al.31 described the prevalence of congenital thrombophilia in 352 women, 119 of them had VTE during or immediately after delivery. In the prevalence of factor V Leiden mutation was 43.7% compared to only 7.7% in control group. Prevalence of prothrombin gene mutation was seen in 16.4% and mixed risk factors were in 9.3% of the cases.

There was no association seen in MTHFR mutation with venous thromboembolism.

**Which Pregnant Women Should be Tested for Thrombophilias?**

Thrombophilia, inherited or acquired is not an uncommon condition. At present, there is no evidence to support routine screening of all pregnant women for thrombophilias. Women with recurrent abortions, with history of stillbirths, early onset of severe preeclampsias, placental abruption, unexplained IUGR should to be tested. Testing should be done before pregnancy is planned or initiated.

All women with past history of DVT or VTE or family history of VTE, stroke, etc. should be tested. About 50% of such women will have thrombophilia.

**Laboratory Investigations**

- Antiphospholipid antibodies—immunoglobulin (Ig) M, IgG, IgA
- Lupus anticoagulant antibody
- Factor V Leiden mutation [deoxyribonucleic acid (DNA) test by polymerase chain reaction (PCR)]
- Hyperhomocysteinemia MTHFR mutation (DNA test by PCR)
- Prothrombin gene mutation G20210A (DNA test by PCR)
- Protein C levels
- Protein S levels
- Activated protein S activity
- Activated partial thromboplastin time (APTT)
- Prothrombin time (PT)
- Partial thromboplastin time (PTT)

**TREATMENT**

There are no clear cut control trials to guide us as to how to manage women with thrombophilia and thus prevent placental thrombosis and severe pregnancy complications. Generally, treatment is not recommended for most pregnant women who are of less severe thrombophilic group such as having factor V Leiden or prothrombin mutation. If there is no history of pregnancy complications or VTE in the past, the risk of development of complications in current pregnancy due to thrombophilia appears to be less than 1% in these women.

Before deciding line of treatment it is essential to know the severity of thrombophilia, as the risk of pregnancy complications are different with the different types. For example the risk of pregnancy associated VTE is higher in women with antithrombin III deficiencies than with the abnormalities of protein C and protein S systems. Previously, unfractionated heparin was used for the treatment of thrombophilia. But nowadays low-molecular-weight heparins (LMWHs) have proved to be more beneficial during pregnancy (Table 4). Before starting the treatment assessment of platele count is mandatory in all cases. Further measurement is done a week after commencing the treatment and thereafter at monthly intervals.

**Thromboprophylaxis**

Women with thrombophilia who have had DVT or VTE in the past should receive prophylactic anticoagulation therapy throughout pregnancy and 4–6 weeks postpartum (Table 4).
Thrombophilia and Preeclampsia

The association of preeclampsia and thrombophilia is also controversial. To date, there are no placebo-controlled trials on prevention of preeclampsia at subsequent gestation with LMWH.

Recently, the Cochrane collaboration35 reported a 15% reduction in the risk of preeclampsia and 14% reduction in the fetal and neonatal deaths with thromboprophylaxis.

Kupferminc et al.36 reported on the use of LMWH in women having thrombophilia with past history of severe preeclampsia, abruptio placentae, IUGR or IUFD (n = 33). They were treated with enoxaparin 40 mg/day and 100 mg aspirin starting from 8 weeks to 12 weeks of gestation. Majority of patients in the study group delivered at the end of 37.6 ± 2–3 weeks whereas patients in other group who had not received thromboprophylaxis delivered at 31 ± 2 weeks. Mean birth weight of the infants in study group was 2,719 ± 526 g whereas in control group it was 1,175 ± 590 g.

Of the 33 women from study group, only three women had preeclampsia in current pregnancy.

Riyazi et al.37 observed no much difference in treated and control group. Acute DVT and VTE in pregnancy with or without thrombophilia is usually treated with full dose of intravenous (IV) heparin for 5–10 days followed by maintenance with subcutaneous (SC) heparin given twice daily, adjusted to prolong the aPTT into the therapeutic range.

Therapeutic Regimens in Patient with APLA Syndrome

Current focus of therapeutic modalities deals with the relative role of heparin compared with aspirin.

A recent study demonstrated an increase in the success rate of pregnancy outcome from 19% to 70% with aspirin therapy.38

The reason as to why some women with APLA respond only to aspirin and others to anticoagulants is still unknown.

Rai et al. (1997)39 reported decrease in the rate of recurrent fetal death to 20.9% when women were treated with aspirin 75 mg plus LMWH enoxaparin 40 mg SC once daily.

During Labor

It is essential to omit the anticoagulant dose at the onset of labor. If the labor is to be induced, then the morning dose should be omitted. Prophylactic dose can be started 6 hours after delivery. In absence of any obstetric indication, vaginal birth is the preferred mode of delivery. There is increased risk of hematoma seen with epidural anesthesia.

During Puerperium

Thromboprophylaxis should be continued for 6 weeks after delivery. In some cases, we may have to continue for 3 months.

For women with protein C and protein S deficiencies or with factor V Leiden having history of VTE in previous pregnancies, anticoagulant prophylaxis with LMWH should be started 4–6 weeks prior to that period of gestation at which the previous incidence occurred. There are no guidelines for anticoagulant prophylaxis with hyperhomocysteinemia. Vitamin B<sub>12</sub>, B<sub>6</sub>, and folic acid supplementation can bring down the homocysteine level, but it is not sure whether it reduces the risk of thrombosis.32

**Thrombophilia and Recurrent Pregnancy Loss**

Data on treatment of women with inherited thrombophilia and pregnancy loss are predominantly uncontrolled and include small series of patients treated mostly with LMWH. A recent collaborative study demonstrated the safety of using LMWH during 486 gestations.33

A successful outcome was reported in 89% of 93 gestations in women with history of recurrent pregnancy loss and in 28 gestations in women who had preeclampsia in previous pregnancy.

Carp et al.34 reported a cohort study undertaken to assess the effect of enoxaparin on subsequent livebirth rates in women with three or more consecutive abortions and hereditary thrombophilia. Livebirth rate in treated group was 26/37 (70.2%) compared to 21/48 (43.8%) in untreated group.

According to different studies, patients with history of recurrent fetal loss should receive prophylactic dose of LMWH in subsequent pregnancy (enoxaparin 0.5 mg/kg or dalteparin 5,000 U) immediately once pregnancy is diagnosed and should continue throughout pregnancy and 6 weeks after delivery.

**Thrombophilia and IUGR**

The association of IUGR and thrombophilia is controversial. Association was demonstrated in women with severe IUGR and not with mild. Data on antithrombotic prophylaxis for IUGR at index pregnancy and on subsequent gestations is limited. However, in view of the risk of recurrence of IUGR with other gestational complications, prophylaxis can be considered.
Thrombophilia in Pregnancy

FUTURE PERSPECTIVES

There are number of issues in the field of thrombophilia which cannot be explained. Even though many tests are available for detection of thrombophilia, in 30–50% of cases the cause for intravascular thrombosis cannot be detected. Whether other genetic or acquired thrombophilia play a role remains to be determined. Complete thrombophilia work-up is costly. Pathogenetic mechanisms responsible for placental vascular pathologies in women with thrombophilia have not been elucidated and it is yet unknown as to why certain women with thrombophilia express vascular gestational pathologies while others do not.

Large prospective trails of antithrombotic modalities are essential to improve the results in women who experience poor pregnancy outcome.

SUMMARY

- Treatment is not recommended in pregnant women having less severe thrombophilia without pregnancy complications in the past.
- Severity of the thrombophilia must be decided.
- Pregnant women with factor V Leiden or prothrombin mutation with history of DVT or VTE must receive thromboprophylaxis.
- Low-molecular-weight heparin is recommended throughout pregnancy and in the postpartum period, in women with severe thrombophilia, (antithrombin III deficiency) or having more than one deficiency even if they had no pregnancy complications or VTE in the past.
- Women with thrombophilia with recurrent pregnancy complications should be treated. Women with APLA syndrome with pregnancy complications are best treated with LMWH plus low-dose aspirin which is more effective than either medication alone, in preventing pregnancy complications.
- Women with mild hyperhomocysteinemia usually respond well to vitamin B<sub>6</sub> and B<sub>12</sub> supplementation. It has been observed that these women may not have the risk of intravascular thrombosis but they may be at an increased risk of pregnancy complications.

INTRODUCTION

Physiologic changes occurring in pregnancy involve nearly every organ system, and the kidneys are no exception. This chapter focuses not only on renal diseases that occur in pregnancy but also on how pregnancy affects chronic renal diseases. Patients with end-stage renal disease (ESRD) requiring renal replacement therapy and patients after renal transplantation pose additional interesting scenarios and possible complications. It is important to ask two questions in the setting of pregnancy and renal disease: How does pregnancy affect kidney disease? How does kidney disease affect pregnancy?

Anatomical Changes in Renal System during Pregnancy

A dilatation of the ureters and pelvis occurs and is presumed to be secondary to the smooth muscle-relaxing effect of progesterone. This dilatation is often more pronounced on the right secondary to dextrorotation of the uterus and dilatation of the right ovarian venous plexus. This can lead to urinary stasis and as discussed later, an increased risk of developing urinary tract infections (UTIs).

There is also an increase in overall kidney size by about 1–1.5 cm.

Physiological Changes in Renal System during Pregnancy

Renal plasma flow increases by 50–70% in pregnancy, and this change is most pronounced in the first two trimesters. This is one of the factors that lead to an increased glomerular filtration rate (GFR). The GFR peaks around the 13th week of pregnancy and can reach levels up to 150% of normal. Therefore, both blood urea nitrogen (BUN) and creatinine levels, the plasma markers of GFR, are decreased. This decrease has clinical significance in that a normal BUN or creatinine level in a pregnant female may actually indicate underlying renal disease.

Similarly, in the initial part of pregnancy, increased levels of progesterone enhance relaxation of the arterial smooth muscles and thus decrease peripheral vascular resistance. Therefore, a blood pressure fall of approximately 10 mm Hg occurs in the first 24 weeks of pregnancy. The blood pressure gradually returns to a prepregnancy level by term. Thus, a consistent normal or prepregnancy blood pressure may suggest the presence of a condition that predisposes patients to hypertension.

A change in tubular function with increased glucosuria also occurs. In addition, a reset in the osmostat occurs, resulting in increased thirst and decreased serum sodium levels (by approximately 5 mEq/L) compared with nonpregnant females.

Effects of progesterone also result in a state of mild respiratory alkalosis and a blood gas of 7.44/30 pCO₂/HCO₃ is representative.

RENAL DISEASE OCCURRING DURING PREGNANCY

Urinary Tract Infections

- Asymptomatic bacteriuria
- Cystitis
- Pyelonephritis

Urinary tract infections are the most common renal disease occurring during pregnancy and range from asymptomatic...
bacteriuria to pyelonephritis. UTIs have been associated with small for gestational age (SGA) babies, premature labor, and intrauterine fetal death.

Pregnant females are at increased risk for development of UTIs, primarily because of the anatomic and physiologic changes that occur in normal pregnancy. As mentioned previously, the collecting system is dilated during pregnancy, most likely secondary to the smooth muscle-relaxing properties of progesterone. This dilatation almost always resolves 2–4 days after delivery. In addition, increased vesicoureteral reflux occurs.

**ASYMPTOMATIC BACTERIURIA**

**Incidence**
- This affects 4–7% of pregnant women, of which up to 40% will develop symptomatic UTI in pregnancy of pregnant women, 2% develop pyelonephritis.
- Women who have a history of previous UTI and are found to have bacteriuria have a tenfold increased risk of developing cystitis or acute pyelonephritis in pregnancy.

**Pathogenesis**
- Seventy-five to ninety percent of bacteriuria in pregnancy is due to *Escherichia coli*, probably derived from the large bowel.
- Colonization of the urinary tract results from ascending infection from the perineum and is related to sexual intercourse.

**Diagnosis**
- Most women with asymptomatic bacteriuria are infected during early pregnancy. Very few subsequently acquire asymptomatic bacteriuria.
- Bacteriuria is only considered significant if the colony count exceeds 100,000/mL on a midstream urine (MSU) specimen.
- Urine culture resulting in a non-significant or mixed growth should be repeated on a fresh MSU specimen.
- Dipsticks for nitrites and leukocyte esterase may be used to help exclude UTI.

**Complications**
- Twenty-five percent develop symptomatic infection during pregnancy
- Increase risk of low birthweight infant
- Preterm delivery
- Pregnancy associated hypertension
- Anemia
- Pyelonephritis
- If bacteriuria that persists or recurs after delivery has been associated with pyelographic evidence of chronic infection, obstructive lesions and congenital abnormalities.

**Management**
- Because dilation of the upper renal tract during pregnancy increases the risk of pyelonephritis asymptomatic bacteriuria should be treated.
- Treating asymptomatic bacteriuria reduces the risk of preterm delivery and low birth weight babies.
- The choice of antibiotic depends on the sensitivities of the causative organism (Table 1).

**ACUTE CYSTITIS**

**Incidence**
Cystitis complicates about 1% of pregnancies.

**Clinical Features**
- These include urinary frequency, urgency, dysuria, hematuria, proteinuria and suprapubic pain.
- Urinary tract infection in pregnancy is more common in diabetics (both with pre-existing and gestational diabetes) and in those receiving systemic corticosteroids.

**Pathogenesis**
- Most infections are due to *E. coli*.
- Keep in mind that symptoms of cystitis and pyuria accompanied by a “sterile” urine culture finding may be the consequence of urethritis caused by *Chlamydia trachomatis*, a common pathogen of the genitourinary tract.
- Mucopurulent cervicitis usually coexists, and erythromycin therapy may be effective.

**Diagnosis**
- This is confirmed by the finding of significant bacteriuria (colony count exceeding 100,000/mL) following culture of a MSU specimen.
- Microscopy of the urine may reveal organisms, white cells and occasionally red cells, but the false-positive rate is very high, therefore it is no longer recommended for diagnosis of UTI.

**Management**
- Antibiotic therapy is guided by sensitivities of the organism. For organisms resistant to penicillins, cephalosporins, nitrofurantoin and trimethoprim; ciprofloxacin may be appropriate but this is not used as first-line therapy in pregnancy.
- Antibiotics should be continued for 5–7 days.
- Several non-pharmacological maneuvers may help prevent recurrent infection in those women troubled by UTIs in pregnancy. These include:
- Increasing fluid intake. This ensures frequent voiding and a high volume dilute urine, all of which reduce the risk of symptomatic infection.
- Emptying the bladder following sexual intercourse. This “washes away” organisms massaged up the urethra from the perineum into the bladder during coitus, before they have a chance to replicate in urine within the bladder.
- Double voiding (to ensure no residual urine is left in the bladder following micturition).
- The perineum should be cleaned from “front to back” following defecation to minimize the risk of bowel organisms colonizing the urethra.

**ACUTE PYELONEPHRITIS**

**Incidence**

- This complicates 1–2% of pregnancies.
- It is more common in pregnancy because of the physiological dilatation of the upper renal tract.

**Clinical Features**

- These include fever, loin and/or abdominal pain, vomiting, rigors as well as proteinuria, hematuria and concomitant features of cystitis.

</table>

**Risk Factors**

- Diabetes
- Steroid therapy
- Polycystic kidneys
- Congenital abnormalities of the renal tract e.g. duplex kidney or ureter
- Neuropathic bladder (e.g. in those with spina bifida or multiple sclerosis)
- Urinary tract calculi.

**Pathogenesis**

The most likely etiologic organisms include E. coli, Klebsiella, Enterobacter and Proteus species.

**Diagnosis**

- This is confirmed by the finding of significant bacteriuria following culture of a MSU specimen.
- Differential diagnosis includes pneumonia (especially right lower lobe), viral infections, cholecystitis and biliary colic, acute appendicitis, gastroenteritis, placental abruption and a degenerating uterine fibroid
- Investigation in women with fever should include blood cultures and a full blood count.

**Pregnancy**

- Acute pyelonephritis increases the risk of premature labor at least in part because of associated pyrexia.
- There is also evidence for an increased risk of low birthweight babies, but this is partly related to an increase in preterm delivery.

**Management**

- This should be undertaken in hospital.
- Once the diagnosis is suspected and a urine sample obtained, antibiotic treatment with appropriate intravenous (IV) antibiotics should begin immediately, before awaiting the results of urine culture or sensitivities.
- Intravenous penicillins or cephalosporins (e.g. Cefuroxime) are usually the first choice, although in the case of septicemia or resistant organisms or women who are allergic to both penicillins and cephalosporins, an aminoglycoside such as gentamicin may be used. There is a theoretical risk of fetal ototoxicity with the use of gentamicin in pregnancy, but provided drug levels are measured and kept within the therapeutic range, this should not be a problem encountered in clinical practice.
- Antibiotics should be given intravenously until the pyrexia settles when they may be changed to an appropriate oral formulation. Antibiotics should be continued for a period of at least 2 weeks.
- Renal function should be checked regularly since renal impairment may complicate acute pyelonephritis in pregnancy, especially, if there is associated sepsis.
Intravenous fluids may also be required, if the woman is volume depleted as a result of vomiting or sweating. An ultrasound examination of the kidneys should be undertaken to exclude hydronephrosis, congenital abnormalities and renal calculi.

**Prophylaxis**

- Women who usually take antibiotic prophylaxis against UTIs should continue this in pregnancy.
- Suitable regimes in pregnancy include low-dose amoxicillin or low-dose oral cephalosporins (cephalexin 250 mg), or nitrofurantoin 50 mg o.d. but depend on the sensitivities of the usual infecting organisms.

**ACUTE RENAL FAILURE**

Acute renal failure (ARF) in pregnancy follows a bimodal distribution. There are peaks in the first trimester (related to unregulated and/or septic abortion) and the late third trimester (related to obstetric complications). The incidence of ARF due to sepsis has fallen significantly in the last 30 years relative to the incidence secondary to obstetric complications (e.g. abruptio placentae, amniotic fluid embolism, postpartum hemorrhage).

Acute renal failure is conventionally and conveniently divided into three categories: (1) prerenal; (2) intrinsic (or “renal”); and (3) postrenal. Sepsis secondary to illegal abortion, while now less common in industrialized nations, is still a common cause of renal failure worldwide. Milder forms of ARF are observed in industrialized countries, and only about 1 case in 15,000 pregnancies requires dialysis.

**Prerenal**

Prerenal causes include the following hypovolemic states:
- Hemorrhage
- Volume depletion from gastrointestinal (GI) or renal losses, burns, fluid sequestration, or low cardiac output states (e.g. chronic heart failure and other diseases of myocardium, valvulopathy, arrhythmia, pericardial diseases, tamponade)
- Systemic vasodilation (e.g. sepsis, anaphylaxis)
- Disseminated intravascular coagulation.
- Sepsis from illegal abortions is often due to *Clostridium welchii*.

**Renal**

**Acute Tubular Necrosis**

- Acute tubular necrosis (ATN) is the most common pathologic finding for ARF in pregnancy.
- Acute tubular necrosis typically occurs after an acute ischemic or toxic event.
- Ischemic ATN is often considered to be a continuum of prerenal azotemia. Indeed, the causes of the two conditions are identical. In pregnancy, these causes are often related to hemorrhage, abruptio placentae, amniotic fluid embolism, and retained dead fetus.
- In addition, nephrotoxic medications are implicated. Remember that gentamicin is occasionally administered in pregnancy, especially in pyelonephritis.

**Cortical Necrosis**

- The presentation of cortical necrosis is similar to that of ATN and is differentiated only by arteriogram and/or biopsy. It was a common finding in ARF because of septic abortion.
- No specific treatment for cortical necrosis is available, so these tests may not be necessary other than for prognostic value.

**Thrombotic Microangiopathies**

- Both thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) can be seen in pregnancy. Incidence of HUS is actually increased in pregnancy, whereas TTP remains the same. Both of these microangiopathies need to be distinguished from hemolysis, elevated liver enzyme levels, and low platelet levels (HELLP) syndrome.
- Plasma exchange is required for both TTP and HUS.

**Postrenal**

- Postrenal causes, i.e. obstructions are rare but must be considered in all patients with ARF because of the ease of reversibility. Diagnosis, however, may be difficult.
- The collecting system undergoes a physiologic dilatation secondary to the smooth muscle-relaxing effects of progesterone. Therefore, ultrasound, which relies heavily on visualization of the dilated collecting system for the diagnosis of obstruction, may be difficult to interpret.
- Use of intravenous or retrograde pyelography may be necessary, realizing that this modality exposes the fetus to radiation.

**Dialysis Requiring Acute Renal Failure**

- Renal failure severe enough to warrant dialysis usually also warrants termination of pregnancy.
- If subacute and if the fetus is still viable, an early initiation (approximately BUN 50) is preferred to prevent uremic insult to the fetus.
- In an effort to prevent dialysis-related hypotension, frequent HD sessions (5–7 sessions/weeks) are scheduled.

**Pregnancy in Pre-existing Renal Disease**

Historically, pregnancy has been commonly regarded as very high-risk to the female with chronic renal disease. Attempts have been made to clarify these risks in the settings of chronic renal insufficiency, dialysis, and transplanted kidneys.
In general, patients receiving dialysis have a marked decrease in fertility, yet pregnancy occasionally occurs. Certainly, a return of fertility in transplant recipients is the rule. These transplant patients have other special considerations, including the use of immunosuppressive medications and the risk of opportunistic infections.

The following discussion addresses pregnancy as it affects patients with chronic renal insufficiency, those with ESRD requiring dialysis, and those who have received a renal transplant. Keep in mind the effects of pregnancy on kidneys and the effects of kidney disease on pregnancy.

CHRONIC RENAL INSUFFICIENCY

Effect of Pregnancy on Chronic Renal Disease

The risks include:
- Possible accelerated decline in renal function
- Escalating hypertension during pregnancy
- Worsening proteinuria during pregnancy.

Increased proteinuria is a physiological response to pregnancy and may not necessarily indicate superimposed preeclampsia or deteriorating renal disease.

Effect of Chronic Renal Disease on Pregnancy

The risks include:
- Miscarriage
- Preeclampsia
- Intrauterine growth restriction (IUGR)
- Preterm delivery
- Fetal death.

Factors Influencing Outcome

The outcome of pregnancy and any adverse effect on underlying renal disease are both influenced by:
- Presence and degree of renal impairment
- Presence and severity of hypertension
- Presence and degree of proteinuria
- Underlying type of chronic renal disease.

In general, women without hypertension or renal impairment prior to conception have successful pregnancies and pregnancy does not adversely influence the progression of the renal disease.

Specific Types of Renal Disease

Glomerulonephritis

- Most pregnancies are successful. Those with hypertension are at increased risk of superimposed preeclampsia.
- Fetal loss and preterm delivery rates are about 20%.
- Less than 10% have a reversible and 3% a progressive decrease in renal function related to pregnancy.
- Over 25% have a reversible and less than 10% have a permanent increase in blood pressure.
- In those with normal renal function at conception, pregnancy does not affect the course of renal disease or the occurrence of ESRD. Hypertension and proteinuria accelerate the rate of decline in renal function, whether or not a woman has been pregnant.

Reflux Nephropathy
- This is one of the most common renal diseases in women of child-bearing age.
- About 25% of women develop preeclampsia and this risk is increased in cases of bilateral renal scarring.
- Even those with normal renal function and without hypertension prepregnancy are at increased risk of hypertension (33%) and preeclampsia (15%).
- Those with renal impairment may experience rapid worsening of renal function.
- There is a particular association between reflux nephropathy in the mother and severe IUGR.
- Reflux nephropathy may be inherited as an autosomal dominant condition, and therefore offspring of affected mothers should be screened with a micturating cystogram, as US may miss the diagnosis.

Diabetic Nephropathy
- Adverse pregnancy outcome and maternal complications are doubled compared to pregnant diabetics without nephropathy.
- The specific risks are UTI, preeclampsia, proteinuria and edema that may be severe but usually revert after delivery to prepregnancy levels.
- Nephrotic syndrome can be severe with marked hypoalbuminemia and the risk of pulmonary edema and thrombosis.
- Over 30% of affected women have preterm deliveries and over 50% have an increase in blood pressure.
- Most women with diabetic nephropathy show the normal increase in GFR and pregnancy does not increase the rate of deterioration in renal function.

Systemic Lupus Erythematosus Nephritis
- In women with lupus nephritis, pregnancy does not seem to jeopardize renal function in the long term, although systemic lupus erythematosus (SLE) nephropathy may manifest for the first time in pregnancy. The risk of deterioration is greater the higher the baseline serum creatinine, although women with moderate renal impairment (serum creatinine > 125 μmol/L) may have uncomplicated pregnancies.
- Pregnancy outcome is particularly affected by renal disease. Even quiescent lupus is associated with increased risk of fetal loss, preeclampsia and IUGR, particularly if there is hypertension or proteinuria.

Polycystic Kidney Disease
- This is an autosomal dominant disorder usually presenting in the fourth decade with hypertension, recurrent UTIs, hematuria or renal impairment. Some asymptomatic women are aware of their diagnosis because of affected family members and positive screening. Women may remain undiagnosed throughout pregnancy.
- The risks in pregnancy are of preeclampsia, which is more common in those with preexisting hypertension or renal impairment, and UTIs. Loin pain and hematuria may occur without UTI.
- Pregnancy has no adverse long-term effect on renal function.
- Polycystic kidney disease (PKD) may be associated with polycystic liver disease and subarachnoid hemorrhage from intracranial aneurysms. Liver cysts may enlarge during pregnancy and those with a family history of intracranial aneurysms should be screened for aneurysms prior to pregnancy.
- Since PKD is an autosomal dominant disorder, there is a 50% chance of transmission to the affected woman’s offspring.

Management of Pregnancies Complicated by Chronic Renal Disease
- Management should begin with prepregnancy counseling. Assessment of preconceptual renal function and blood pressure enables accurate counseling and provides a baseline with which to compare trends in pregnancy.
- Obstetricians and physicians who have expertise in the care of renal disease in pregnancy should manage jointly women with chronic renal disease.
- In view of the increased risk of preeclampsia, treatment with low-dose aspirin should be considered, especially in those with hypertension and renal impairment or a previous poor obstetric history.
- Careful monitoring and control of blood pressure both in prepregnancy and antenatally is important. Treatment for blood pressure problems is no different from the management of pregnant women without renal disease. However, the threshold for treatment may be lower, since good control of hypertension is important to preserve renal function.
- Regular assessment of renal function by creatinine clearance and 24-hour protein excretion, as well as serum creatinine and urea is essential. It may useful to give

| Table 3: Effect of degree of renal impairment on pregnancy outcome |
|-------------------|------------------|------------------|
|                   | Mild Cr < 125 | Moderate Cr = 125–249 | Severe Cr > 250 |
| Preeclampsia      | 25%            | 50%              | 85%             |
| IUGR              | 30%            | 60%              | 70%             |
| Preterm           | 55%            | 60–90%           | 20–30%          |
| Success           | 85–95%         | 60–90%           | 20–30%          |

Abbreviations: Cr, creatinine in μmol/L; IUGR, intrauterine growth restriction
the woman urine testing strips so she can monitor the presence and severity of any proteinuria or hematuria.

- The fetus should be monitored with regular US assessment of growth and Doppler assessment of uterine and umbilical circulation.
- Admission should be considered, if the woman develops worsening hypertension, deteriorating renal function or proteinuria, superimposed preeclampsia, or polyhydramnios.
- The differentiation between preeclampsia and deterioration of preexisting renal disease may be extremely difficult. However, the indications for renal biopsy during pregnancy are mostly limited to situations where a delay before delivery is desirable (i.e. before 32 weeks' gestation) and a diagnosis of a steroid or chemotherapy-sensitive lesion is suspected.

**PREGNANCY IN DIALYSIS PATIENTS**

- Fertility is reduced in women on hemodialysis or chronic ambulatory peritoneal dialysis (CAPD). The pregnancy rate is about 1 in 200 women per year.
- The chance of successful pregnancy outcome is low (30%) with both hemodialysis and CAPD.
- Poor prognostic features for pregnancy in dialysis patients include:
  - Age more than 35 years
  - More than 5 years on dialysis
  - Delayed diagnosis of pregnancy (leading to late increase in dialysis times).

**Effect of Pregnancy on Renal Replacement Therapy**

- Anemia is exacerbated by pregnancy. Transfusion requirements increase. Erythropoietin and iv iron may be safely used and increased in pregnancy.
- Pregnancy is associated with markedly increased requirements for dialysis.
- Doses of heparin may need to be increased to prevent clotting of dialysis lines.
- Pregnancy causes fluctuations in fluid balance and blood pressure.
- Doses of vitamin D and calcium may need to be reduced.

**Effect of Dialysis on Pregnancy**

The risks include:
- Miscarriage
- Intrauterine death
- Hypertension and preeclampsia
- Preterm labor
- Preterm rupture of membranes
- Polyhydramnios related to uremia
- Placental abruption.

Full heparinization requirements during hemodialysis increase the risk of bleeding. The specific problems with GAPD include peritonitis.

**Management**

In women on hemodialysis, the duration and/or the frequency of dialysis must be increased, to more than 20 hours/week. The aim should be to maintain the pre-dialysis urea at less than 15–20 µmol/L.

Dietary restrictions can usually be lifted, although continued adherence fluid restriction is important to avoid large fluid shifts during dialysis.

**Renal Transplant Recipients**

- Women receiving renal transplants should be warned that as renal function returns to normal, ovulation, menstruation and fertility also resume.
- Women desiring pregnancy are usually advised to wait about 1–2 years after transplantation, by which time graft function has stabilized and maintenance levels of immunosuppressive drugs will have been reached, thus minimizing any risk to the fetus.
- Survival is improved for recipients of living, related donors compared to cadaveric donors.
- Successful pregnancy outcome for those transplant recipients who become pregnant and do not miscarry before 12 weeks is now 95%.
- As with chronic renal impairment, pregnancy outcome and effects on the renal allograft are both dependent on the baseline serum creatinine level and the presence of hypertension; the poorer the graft function at conception, the higher the risk of complications and deterioration in graft function.

**Effect of Pregnancy on Renal Transplants**

- Pregnancy has no adverse long-term effect on renal allograft function or survival in women with baseline creatinine levels of less than 100 µmol/L.
- For women who enter pregnancy with a serum creatinine level more than 130 µmol/L renal graft survival is only 65% at 3 years.
- Renal allografts adapt to pregnancy in the same way as normal kidneys, and exhibit an increase in GFR and collecting-system dilatation. As with normal kidneys, the GFR may decrease again in the third trimester.
- About 15% of women develop significant impairment of renal function during pregnancy and this may persist after delivery.
- About 40% of women develop proteinuria towards term, but this usually regresses postpartum.
- More than 10% of women are likely to develop new long-term problems following pregnancy, although whether this
is as a direct result of pregnancy is difficult to ascertain. The risk of long-term problems is higher in women developing pregnancy complications prior to 28 weeks’ gestation.

- About 10% of women will die within 1–7 years after pregnancy, and about 50% within 15 years.

**Effect of Renal Transplants on Pregnancy**

- Outcome is optimal in those without hypertension, proteinuria, recent episodes of graft rejection, and in those with normal or near-normal renal function (serum creatinine level < 125 µmol/L).
- The chance of successful outcome beyond 12 weeks is 97% with a baseline creatinine level less than 125 µmol/L, but this is reduced to 75% if the baseline creatinine level is more than 125 µmol/L.
- The complication rate is higher for diabetics, and those with poor graft function.
- The incidence of problems in pregnancy is about 50% and includes:
  - Hypertension/preeclampsia (30%)
  - Graft rejection (10%)
  - IUGR (20–40%)
  - Preterm delivery (45–60%)
  - Infection, especially UTI.

**Antenatal Management**

- Women should be managed jointly by nephrologists and obstetricians with expertise in the care of pregnant renal transplant recipients.
- Careful monitoring and control of blood pressure is important.
- Regular assessment of renal function by creatinine clearance and 24-hour protein excretion, as well as serum creatinine and urea is essential.
- A full blood count and liver function tests should also be checked regularly. Anemia is common and hematinsics should be prescribed. Maternal hypocalcemia and hypercalcemia are both potential problems, and calcium status should be carefully monitored. Doses of calcium and vitamin D may need to be altered in pregnancy.
- An MSU specimen should be taken and sent at each visit and any infection treated promptly. Some women require prophylactic antibiotics.
- Cytomegalovirus (CMV) titers should be checked in each trimester if the woman is CMV negative at the onset of pregnancy.
- The fetus should be monitored with regular USG assessment of growth and Doppler assessment of uterine and umbilical circulation.
- Provided proteinuria is not accompanied by deteriorating renal function or hypertension, this is not an indication for delivery.

- The differential diagnosis of deteriorating renal function includes:
  - Reversible causes, e.g. infection (e.g. UTI), dehydration
  - Preeclampsia
  - Cyclosporin nephrotoxicity
  - Acute and/or chronic rejection.

- The features of acute rejection include:
  - Deteriorating renal function
  - Fever
  - Oliguria
  - Graft swelling and tenderness
  - Altered echogenicity of renal parenchyma and blurring of corticomedullary junction on ultrasound.

- Definitive diagnosis of rejection is only possible with renal biopsy.

**Immunosuppressive Therapy**

- The levels of immunosuppressive drugs are maintained at prepregnancy levels. Regimes vary but include treatment with:
  - Prednisolone
  - Azathioprine
  - Cyclosporin
  - Tacrolimus

- **Mycophenolate mofetil**: This is contraindicated in pregnancy and effective contraception is required during and for 6 weeks after discontinuation of treatment.
- Women require reassurance regarding the relative safety of their drugs, as reduction or cessation of immunosuppressive therapy may provoke rejection
- Azathioprine dose may be monitored via maternal white-cell count.
- Both cyclosporin and tacrolimus appear to be safe for use in pregnancy. Plasma levels should be measured regularly.
- Mycophenolate mofetil (MMF) is teratogenic and women desiring pregnancy should be converted to azathioprine prior to conception. They should be counseled regarding possible detrimental effects on graft function from a change in therapy. In some cases discontinuation of MMF, and therefore pregnancy, is contraindicated.
- Pregnancy success rates are similar in women taking azathioprine cyclosporin, but the incidence of IUGR is higher (30–40% versus 20%) in women taking cyclosporin.

**Delivery**

- Cesarean section is only required for obstetric indications, although overall section rate is increased (25%) compared to background rates, renal allograft does not obstruct vaginal delivery.
- Prophylactic antibiotics should be given to cover any surgical procedure including episiotomy.
- Parenteral steroids are necessary to cover labor, as with any woman on maintenance steroids.
Neonatal Problems

These are largely related to prematurity but also include the following:
- Thymic atrophy
- Transient leukopenia or thrombocytopenia
- Depressed hemopoiesis
- Adrenocortical insufficiency
- Septicemia
- Cytomegalovirus and hepatitis B infection.

Congenital abnormalities are no more common in the offspring of mothers taking antirejection doses of the earlier mentioned immunosuppressive drugs.

BIBLIOGRAPHY

HIV Infection in Pregnancy

The human immunodeficiency virus (HIV) continues to devastate populations throughout the world, and poses as one of the most vexing public health problems of the twentieth and twenty-first centuries.

According to the latest update on the worldwide acquired immunodeficiency syndrome (AIDS) epidemic from the Joint United Nations Program on HIV/AIDS, the global population of women living with HIV/AIDS grew by 1.2 million between 2004 and 2006 to a total of 17.7 million, or 48% of the total population of adults living with HIV.

This increasing prevalence among adult women has been observed in every region and country, including India. This is in contrast to earlier times in the epidemic when HIV and AIDS were seen much less frequently among women than among men.

According to the National AIDS Control Organisation, with 27 million pregnancies a year and an overall estimated 0.3% prevalence rate of HIV infection among pregnant women, it is estimated that about 100,000 HIV infected women deliver every year in India.

Moreover, the majority of these cases occur in women between 15 years and 39 years of age, the period during which childbearing potential is greatest.

The intervening period has seen significant advancement in the use of antiretroviral therapy that has extended life expectancy among HIV-infected patients and reduced the risk of mother-to-child HIV transmission to less than 1% especially in resource rich settings. As a result, HIV-infected women may not differ substantially from uninfected women regarding reproductive patterns or their intention to have children.

A survey of 118 HIV-positive women 18–46 years of age who were receiving care at a US-based HIV care center in 2004 found that one-third wished to have a child in the future.

It is recognized that mother-to-child transmission remains a significant driver of the global HIV/AIDS epidemic because of disparities in healthcare provision. This chapter describes strategies to manage conception, pregnancy, and reproductive health in HIV-infected women in India, both in well-resourced healthcare settings and resource constrained settings.

REPRODUCTIVE HEALTH ISSUES IN HIV-INFECTED WOMEN

Although no data is available on pregnancies that occur unplanned in India, but approximately one half of all pregnancies that occur in the United States are unplanned.

As a result, the US Department of Health and Human Services, guidelines on reducing perinatal HIV transmission includes new recommendations regarding the provision of preconception counseling to all HIV-infected women as a regular component of their ongoing care.

The aim of this intervention is to improve women’s health before conception and to provide education to reduce the risk of adverse maternal or infant outcomes.

METHODS OF CONCEPTION IN HIV-INFECTED PATIENTS

Ethically all doctors share responsibility with HIV-infected patients for the safety of uninfected partners and of potential offspring.

Patients who wish to bear their own genetically related children should be referred to specialist institutions for evaluation, treatment, and follow-up. Alternatively, patients may be advised to consider other options, such as the use of donor sperm, adoption, or not having children. If reproductive counseling and care are not provided, it must be anticipated
that some women will try to conceive through unprotected sex, presenting a potential risk of HIV transmission or superinfection. The risk of HIV transmission from male to female has been estimated to be about 1/1,000, approximately eight times more efficient than female-to-male transmission.11

Longitudinal studies that have evaluated the risk of HIV transmission between discordantly infected heterosexual couples who were counseled regarding condom use have reported seroconversion rates between 3% and 8% per 100 person-years of observation in couples who used condoms either inconsistently or not at all.12-15 In a European study, the estimated cumulative incidence of seroconversion at 24 months among 121 discordant couples who used condoms inconsistently was 12.7% [95% confidence interval (CI): 5.9-19.5], and the rate did not differ between male and female index partners.12 Investigators for the Ugandan Rakai Project Study Group have reported that the HIV-1 ribonucleic acid (RNA) level is an important predictor of risk of HIV transmission between discordant couples and that transmission appears to be rare among persons with HIV-1 RNA less than 1,500 copies/mL.16

Viral shedding in semen, however, is intermittent and correlates poorly with plasma HIV-1 RNA.17 Unprotected sex thus remains a potential mode of HIV transmission between discordant partners even when effective highly active antiretroviral therapy (HAART) has reduced plasma HIV-1 RNA to undetectable levels in the HIV-infected partner. To avoid this risk, alternative methods of conception can be presented to patients who are considering pregnancy, according to the HIV status of the respective partners.

**HIV-Positive Female with HIV-Negative Male**

In discordantly infected couples in which the female is HIV positive and the male is HIV negative, artificial insemination of husband semen is an appropriate conception method that protects the male from HIV infection.

**HIV-Negative Female with HIV-Positive Male**

In this scenario, where it is important to protect the female partner from HIV infection, methods of semen processing (sometimes known as “sperm washing”) may be considered, where such services are available. The aim of semen processing is to separate sperm, which lack HIV-1 receptors, from seminal plasma and nonsperm cells, which may harbor virus. The separated sperm fraction is then assayed to confirm absence of HIV-1 RNA using a polymerase chain reaction (PCR) method and to verify the quality of the sperm before either intrauterine insemination, in vitro fertilization, or intracytoplasmic sperm injection. There is no consensus on the optimal method of semen processing for use in HIV-infected men,17 although there is some evidence that techniques are more effective in removing virus from semen in men who are receiving HAART compared with untreated men.18 Where provided by specialist centers, however, semen processing and assisted reproduction techniques offer discordantly infected couples the chance to conceive with a greatly reduced risk of HIV transmission to the uninfected female. A recent report from Savasi and colleagues19 described outcomes in 741 couples (HIV-positive male with HIV-negative female) who received sperm washing plus either intrauterine insemination or in vitro fertilization/intracytoplasmic sperm injection. The overall pregnancy rate was 70.3%, and all female partners remained HIV negative during follow-up.

**HIV-Positive Female with HIV-Positive Male**

In cases where both partners are HIV-positive, semen processing and donor insemination may also be considered to avoid the risk of HIV superinfection.

**EFFECTS OF PREGNANCY ON HIV INFECTION**

CD4+ cell counts decline during pregnancy but typically return to baseline following delivery.20 Plasma HIV-1 RNA tends to remain stable in pregnancy but then increases in the postpartum period.21 However, there is little evidence that pregnancy adversely affects clinical disease outcomes. A systematic review of data from seven prospective cohorts on the impact of pregnancy on HIV disease progression and survival found no significant differences in risk of death, HIV disease progression, or decline of CD4+ cell count to less than 200 cells/mm³ among pregnant versus nonpregnant HIV-infected women, although there might have been some increase in the risk of progression to an AIDS-defining illness among pregnant women (odds ratio: 1.63; 95% CI: 1.00-2.67).22

A separate study investigating disease outcomes in HIV-infected women who had single or multiple pregnancies found that repeat pregnancies had no significant impact on disease progression.23

**EFFECTS OF HIV INFECTION ON PREGNANCY**

Without intervention, HIV infection is efficiently transmitted from mother to child. Before the use of antiretroviral prophylaxis, reported vertical transmission rates ranged from 13% to 32% in industrialized countries and from 25% to 48% in resource-poor settings.24 Transmission may occur at any time during gestation, although evidence suggests that in the absence of any preventive measures, most transmission events occur during the intrapartum period.25 Several factors are known to influence the likelihood of vertical HIV transmission. These can be divided into factors related to HIV disease, health and social factors related to the mother, factors related to the delivery, and infant factors.
Antiretroviral therapy and avoidance of breastfeeding are the primary interventions that reduce the risk of mother-to-child HIV transmission. In 1994, results from the pediatric AIDS clinical trials group (PACTG) 076 trial were published showing a multicomponent zidovudine regimen reduced mother-to-child HIV transmission by nearly 70% (Table 1).

Later that year, the US Public Health Service (USPHS) issued guidelines for the use of zidovudine to reduce perinatal HIV transmission. The PACTG 076 study and the subsequent USPHS recommendations spurred a dramatic decline in the number of perinatal AIDS cases in the late 1990s. Clinical trials and observational studies in developed countries, as well as clinical trials of shorter course regimens in low resource settings, have demonstrated that a variety of antiretroviral regimens reduce the risk of maternal-child HIV transmission, with the greatest risk reductions seen with longer duration and more complex regimens (Fig. 1). With the use of combination antiretroviral therapy during pregnancy (Table 2) and the achievement of very low or undetectable maternal HIV RNA levels (at the time of delivery or near delivery), perinatal transmission of HIV occurs in fewer than 1–2% of women, in contrast with the transmission rate of 20–25% in women who receive no antiretroviral therapy (Fig. 2 and Table 3). The use of antiretroviral therapy may provide significant benefit even if the pregnant woman does not achieve an undetectable HIV RNA level. Among women with comparable low-level detectable HIV RNA (less than 1,000 copies/mL) at the time of delivery, those who received antiretroviral therapy (during pregnancy, at the time of delivery, or both), had a significantly lower rate of HIV transmission compared with those who received no antiretroviral therapy. Thus, it appears that antiretroviral therapy decreases maternal-child HIV transmission via multiple mechanisms, including those dependent and independent of HIV RNA levels. Taken together, available data clearly show that antiretroviral therapy significantly reduces the risk of maternal to child HIV transmission, and these data justify recommendations to use antiretroviral therapy for all HIV-infected pregnant women during pregnancy.

Fig. 2: Effect of no antiretroviral therapy (ART), mono, dual or multi-drug ART regimens on mother-to-child transmission of HIV infection
GUIDELINES FOR USE OF ANTIRETROVIRAL THERAPY IN PREGNANCY

Guidelines in this chapter will focus on four major clinical scenarios (Fig. 3) in which antiretroviral therapy can be used to reduce maternal to child transmission of HIV:

1. A woman who is newly diagnosed with HIV in pregnancy
2. HIV-infected woman is receiving antiretroviral therapy that was started before she became pregnant
3. HIV-infected woman is in labor and has not received prior antiretroviral therapy
4. An infant is born to an HIV-infected woman who has received no antiretroviral therapy during pregnancy or in the intrapartum period.

The following discussion will focus on management issues related to the above four major scenarios that involve the use of antiretroviral therapy during pregnancy. All HIV-infected pregnant women, regardless of what regimen they receive during pregnancy, should receive zidovudine during labor, and the newborn should receive zidovudine by oral suspension for the first 6 weeks of life.9

SCENARIO 1

Approach to Women Who is Newly Diagnosed with HIV in Pregnancy

When an antiretroviral therapy-naïve HIV-infected woman becomes pregnant or is newly diagnosed with HIV in pregnancy, she should promptly undergo clinical, immunologic, and virologic evaluation. In this scenario, many experts would recommend deferring initiation of antiretroviral therapy until after the first trimester to minimize fetal exposure at the most vulnerable period of development. If, however, the clinical or immunologic condition of the woman indicates the need for more immediate initiation of therapy, effective combination antiretroviral therapy should be started.9 When the pre-antiretroviral therapy HIV RNA level exceeds 1,000 copies/mL, combination antiretroviral therapy is recommended, regardless of the patient’s CD4 cell count or clinical status. In addition, the pregnant woman should receive combination antiretroviral therapy, if she has an indication for antiretroviral therapy based on her immunologic status. Although zidovudine monotherapy with the three-part regimen used in the PACTG 076 study would be considered acceptable in women who have a CD4 count greater than 350 cells/mm³ and HIV RNA less than 1,000 copies/mL, data from PACTG 367 suggest that combination therapy achieves an even lower rate of HIV transmission.34

In addition, the use of zidovudine monotherapy during pregnancy can result in the development of resistance to zidovudine and can thus negatively affect future antiretroviral therapy options.

SCENARIO 2

Approach to HIV-Infected Pregnant Women Receiving Antiretroviral Therapy that was Started before She Became Pregnant

In the second scenario involving an HIV-infected woman who becomes pregnant while taking antiretroviral therapy, most experts would recommend continuing therapy, especially if the woman has already entered the second or third trimester of pregnancy. If, however, the woman is still in the first trimester, the risks and benefits of continuing therapy should be discussed in detail with her. In some instances, antiretroviral therapy may need to be interrupted in the first trimester if the woman has significant nausea and vomiting, a situation that may create problems with adherence and proper absorption. If, for whatever reason, antiretroviral therapy is discontinued during the first trimester, all antiretroviral medications should be stopped in a pattern to avoid the development of resistance and then restarted at the onset of the second trimester. If the regimen includes efavirenz or nevirapine, most experts would recommend discontinuing these drugs several days prior to other medications in the regimen because of their very long half-life and low genetic barrier to developing resistance; in this situation, the clinician should ideally consult with an expert in antiretroviral therapy. If the decision is made to continue antiretroviral therapy during the first trimester, and the woman’s existing regimen contains efavirenz, another effective agent should replace efavirenz, because of the increased risk of neural tube defects associated with first trimester exposure to this drug.35,36 Some experts would consider the use of efavirenz in the second or third trimester acceptable, if no other effective antiretroviral option existed. In addition, if therapy is to be continued, but
the existing regimen does not include zidovudine, many experts would recommend substituting zidovudine for one of the nucleoside (or nucleotide) reverse transcriptase inhibitors (if this would be likely to maintain optimal effectiveness) or adding zidovudine to an existing regimen, mainly because of the extensive data with zidovudine in preventing maternal-child HIV transmission.

Specific Drug Recommendations for Use in Pregnancy

Most of the same general principles exist when choosing antiretroviral regimens for use during pregnancy as when choosing regimens for HIV-infected adults and adolescents who are not pregnant. Consensus guidelines all over world recommend antiretroviral therapy for HIV-infected pregnant women consisting of combination therapy with three or more antiretroviral medications, typically two nucleoside reverse transcriptase inhibitors (NRTIs) plus a protease inhibitor (PI). These guidelines categorize antiretroviral drugs in pregnancy as either recommended, alternative, those for which insufficient data exists, and those not recommended. These categorizations are based on experience (or lack of experience) and available data with these medications related to safety and effectiveness in reducing perinatal HIV transmission. Any decision regarding regimen selection should also include consideration of effectiveness for maternal treatment. The preferred dual NRTI backbone consists of zidovudine combined with lamivudine, most often given as the fixed-drug preparation. The preferred PIs include either nelfinavir or saquinavir boosted with ritonavir. As noted above, the use of efavirenz should be avoided during pregnancy. Although the use of single or dual NRTIs alone is not recommended for treatment of HIV infection, zidovudine monotherapy is considered acceptable for prophylaxis of perinatal transmission in pregnant women who have a baseline HIV RNA less than 1,000 copies/mL and who do not meet CD4 criteria for initiating antiretroviral treatment. The clinician should also be aware of several special considerations when using antiretroviral agents in pregnancy: (1) pharmacokinetics may be altered during pregnancy; (2) antiretroviral therapy toxicity and side effects may be altered in pregnancy, or may be more easily overlooked; and (3) potential fetal and newborn toxicity, such as birth defects, carcinogenicity, anemia and mitochondrial toxicity must be considered, since these could potentially occur with babies exposed to these drugs in utero, irrespective of their HIV status.

Special Risk with Antiretroviral Therapy during Pregnancy

Women initiating nevirapine with a CD4 greater than 250 cells/mm³ have a tenfold increased risk of developing symptomatic, often rash-associated hepatotoxicity and hepatic failure, usually within the first 18 weeks after starting nevirapine. These adverse reactions to nevirapine have included several deaths among pregnant patients. Although women who enter pregnancy on a well-tolerated nevirapine-containing regimen may continue on this regimen, initiating nevirapine-containing combination therapy in women with a CD4 count greater than 250 cells/mm³ should be avoided. Although it is recommended that whenever possible antenatal antiretroviral therapy should include zidovudine as part of the regimen, zidovudine is associated with bone marrow suppression and pregnant women are more likely to be anemic. Accordingly, severe anemia constitutes a relative contraindication for using zidovudine, unless a transfusion is given. Stavudine is considered an alternative NRTI in pregnancy and can substitute for zidovudine, as in the patient in this case. The combination of stavudine and didanosine has been associated with several cases of lactic acidosis, some fatal, in pregnancy and should not be used unless no other options are available. Sparse data exist regarding the use of tenofovir, abacavir, or emtricitabine during pregnancy. Tenofovir has become a very commonly used agent for nonpregnant HIV-infected persons, but its use in pregnancy remains limited because of concern regarding potential fetal bone effects. Among the protease inhibitors, there are some concerns with indinavir and atazanavir use late in pregnancy, mainly because these drugs can increase indirect bilirubin levels and thus theoretically exacerbate physiologic hyperbilirubinemia in the neonate. Although there are concerns with maternal toxicity resulting from antiretroviral therapy, the benefits of therapy in preventing perinatal transmission and improving maternal health when maternal treatment is indicated far outweigh the risks.

SCENARIO 3

Presentation in Labor with No Prior Antiretroviral Therapy (Applicable in Settings where Mothers do not Access Prenatal Care or where HIV Testing is not Offered)

Use of Rapid HIV Testing for Women in Labor

Unfortunately, some HIV-infected women present at the time of labor and delivery without having undergone prior HIV testing. For those women, who present at the time of labor without prior HIV testing, rapid HIV testing now provides a means to promptly identify previously undiagnosed HIV-infected women in whom antiretroviral therapy could provide substantial benefit in reducing maternal-to-child HIV transmission. In the mother-infant rapid intervention at delivery (MIRIAD) study, which involved women in labor with undocumented HIV status, rapid HIV testing was well received, feasible and performed with greater than 99% sensitivity and specificity. Based on these results, along with
strong evidence that antiretroviral interventions can reduce the risk of perinatal HIV transmission when initiated in labor, rapid HIV testing is recommended for all women in labor who have undocumented HIV status after consent.53,54 If a woman in labor has a positive rapid HIV test, the clinician should initiate antiretroviral prophylaxis using zidovudine without waiting for the confirmatory HIV antibody test result.

Antiretroviral Prophylactic Regimens with Presentation in Labor

Because most maternal-to-child HIV transmission occurs shortly before or during labor, HIV-infected women who present in labor with no prior antiretroviral therapy can still derive major benefit from receiving antiretroviral therapy. The decision regarding whether the mother should undergo cesarean delivery in this setting is discussed in detail separately in the last section. The 2006 Public Health Service Task Force Guidelines lists four possible intrapartum and postpartum antiretroviral regimens for use when started in labor.55 Epidemiologic data have established benefit for women presenting in labor with the use of zidovudine alone,47 and clinical trials in sub-Saharan Africa have established benefit in similar situations for the combination regimen of zidovudine plus lamivudine and with nevirapine monotherapy.7,9 In addition, zidovudine plus nevirapine is listed as a theoretically effective regimen. After the publication of these guidelines, results from a trial in Africa showed similar transmission rates when infants received single-dose nevirapine with or without 1 week of zidovudine;60 in both groups, the mothers received single-dose nevirapine prior to birth if they presented early in labor.49 In the western world, the most commonly used regimen for women presenting in labor consists of zidovudine by intravenous infusion during labor and delivery followed by 6 weeks of zidovudine oral suspension for the newborn. This regimen is the same as the second and third components of the PACTG 076 protocol.29 Although, it is difficult to compare results between clinical trials and observational studies and between those conducted in the western countries and those in low resource countries where HIV-infected mothers often breastfeed, zidovudine appears to be equal to or superior to other regimens that have been studied for use in this setting.

Nevirapine Monotherapy with Presentation in Labor

In resource constrained areas, there has been major interest and investigation in simple, cost-effective regimens that do not require the use of intravenous zidovudine or the prolonged administration of zidovudine to the infant. Nevirapine given as a single dose to the mother at the onset of labor and as a single dose to the infant within the first 48–72 hours of life reduced maternal-to-child transmission rates by approximately 50% in the HIV NET 012 clinical trial in Uganda.46 It is inexpensive, simple and has a good safety profile (hepatotoxicity has not been described with use of single-dose nevirapine). There are, however, increasing concerns with this regimen because of the high rates of non-nucleoside reverse transcriptase inhibitor (NNRTI) resistance that have been documented in both mother and child after only one dose or two doses of nevirapine.50–52 The development of resistance is thought to result from the long half-life of nevirapine with significant blood levels detectable for up to 3 weeks after a single dose53,54 resulting essentially in prolonged monotherapy with an agent that has a low genetic barrier to resistance. Development of resistance may affect subsequent response to NNRTI-based regimens given for maternal therapy55 and secondary transmission of resistant strains to partner. The recent trial from Africa noted above clearly showed a lower rate of infant NNRTI resistance when the infants took a 1-week course of zidovudine in addition to the single dose of postpartum nevirapine.45 This study, however, did not address maternal NNRTI resistance, nor did it address the impact of adding other antiviral agents, such as zidovudine, to the single dose intrapartum nevirapine. Another recently published trial from Africa showed very low rates of maternal and infant NNRTI resistance with a prepartum regimen of zidovudine plus lamivudine (started at week 32 of gestation), an intrapartum regimen of single dose nevirapine, zidovudine and lamivudine given at the onset of labor, and a postpartum regimen of zidovudine plus lamivudine given to the infant for 3 days after birth combined with a single dose of nevirapine given on the second day.56 Taken together, the available data strongly suggest that nevirapine monotherapy should be used only if other intrapartum prophylactic regimens are not available.

SCENARIO 4

An Infant is Born to a HIV-infected Woman Who has Received no Antiretroviral Therapy

Impact of Neonatal Antiretroviral Therapy

Since the mid-1990s, maternal-child transmission of HIV has markedly declined. As a result, the number of perinatally-acquired AIDS cases has also dramatically declined.27 Most of this success can be attributed to universal HIV counseling and voluntary HIV screening during prenatal care, combined with the use of antiretroviral therapy during pregnancy and labor. In 1994, the PACTG protocol 076 demonstrated a nearly 70% decrease in the risk of vertical HIV transmission to newborn infants with the use of a three-part zidovudine regimen that consisted of oral zidovudine initiated at 14–34 weeks gestation (antepartum), intravenous zidovudine given during labor (intrapartum) and oral zidovudine administered for 6 weeks to the infant (postpartum).28 Although this study did not
delineate the relative importance of each of the components of the zidovudine regimen, subsequent work has established that most maternal-to-child HIV transmission occurs close to or during the time of labor and delivery.\textsuperscript{23}

Currently, it remains unclear whether the third component of PACTG 076—oral zidovudine given for 6 weeks to the newborn—plays a significantly role in reducing maternal-to-child HIV transmission. One epidemiologic study that involved infants whose mothers did not receive antepartum or intrapartum zidovudine failed to show benefit from neonatal zidovudine.\textsuperscript{57} In contrast, a retrospective study suggested a benefit in this setting if the neonate started receiving zidovudine shortly after birth (most within 12 hours).\textsuperscript{58} Data from Africa have demonstrated conflicting results regarding the benefit of short-course neonatal zidovudine when given in addition to single dose neonatal nevirapine.\textsuperscript{59,60} Thus, further study is required to better define the impact of neonatal antiretroviral therapy on maternal-to-child HIV transmission and the optimal regimen in this setting.

**Recommendations for Neonatal Antiretroviral Therapy**

Despite the limitations that exist in our understanding of the benefit of neonatal antiretroviral therapy, the current guidelines recommend that infants born to HIV-infected women should receive a 6-week course of zidovudine with the recommended dosing for infants born at 35 weeks gestation or later consisting of 2 mg/kg of zidovudine syrup given orally every 6 hours.\textsuperscript{7} The infant should receive the first zidovudine dose as soon as possible after birth, preferably within 6–12 hours. For those infants born at less than 35 weeks gestation (but after 30 weeks) at delivery, the zidovudine should initially be dosed every 12 hours; the zidovudine dose interval should then change to every 8 hours after 2 weeks of age.\textsuperscript{61} If the neonate was less than 30 weeks gestation at birth, the dosing interval should change after 4 weeks of age. For HIV-infected mothers with known or suspected zidovudine resistance, some experts would recommend using an alternative to zidovudine, either as monotherapy or combination therapy.\textsuperscript{61,62} Nevertheless, use of drugs other than zidovudine or combination therapy have not been shown to be more beneficial than zidovudine monotherapy in the setting of suspected or known zidovudine resistance. If combination therapy is used in this setting, expert consultation is recommended. Those infants who receive zidovudine should undergo hematologic monitoring consisting of a complete blood count with differential at baseline, at the end of the 6 weeks course, and, if an earlier value is abnormal, again at 12 weeks. Those infants with anemia at birth should undergo more intensive monitoring. Infants who receive combination antiretroviral therapy should have expanded monitoring that also includes serum chemistry, hepatic transaminase levels and serum bilirubin levels.

**PERINATAL HIV TRANSMISSION AND ROUTE OF DELIVERY**

**Background**

The last two decades has seen significant improvements in the therapeutic options for HIV-infected individuals, resulting in increased longevity and improved quality of life. Concomitant with these improvements in therapy, there has been an increase in the number of perinatally HIV-infected women anticipating the birth of their own children.\textsuperscript{63} Although reducing the risk of vertical transmission is a primary concern, it is important to keep in perspective the patient’s commitment to taking the medications, her likely adherence while taking antiretroviral medications, and the potential long-term implications of non-adherence. If effective HAART is taken during pregnancy, the risk of maternal-to-child HIV transmission is very low.\textsuperscript{30} Unfortunately, in some situations, pregnant HIV-infected mothers may go through pregnancy without taking antiretroviral therapy. In such scenarios, efforts to prevent HIV transmission at the time of delivery are of paramount importance. Indeed, it is estimated that among newborns with perinatally-acquired HIV, approximately 60% become infected during labor and delivery.\textsuperscript{64} The mother-to-child transmission of HIV that occurs during labor and delivery is believed to result from transplacental maternal-fetal microtransfusion of blood during uterine contractions and fetal exposure to maternal cervicovaginal secretions and blood during delivery.\textsuperscript{65} Investigators have identified a number of factors prior to and during delivery that may affect the risk of HIV transmission. The remaining discussion will focus on the impact, indications, timing, and complications of cesarean section delivery in HIV-infected mothers, as well as use of antiretroviral therapy administered during delivery.

**Impact of Cesarean Section on Perinatal HIV Transmission**

Prior to the widespread use of viral load testing and the use of combination antiretroviral therapy during pregnancy, several studies clearly established that cesarean section, if performed before the onset of labor and rupture of membranes, significantly reduces perinatal transmission of HIV when compared with other modes of delivery.\textsuperscript{3,66} In 1999, the international perinatal HIV group published the findings of a meta-analysis of 15 prospective cohort studies that addressed the impact of elective cesarean section versus vaginal delivery on the risk of mother-to-child HIV transmission.\textsuperscript{66} These studies involved a cumulative total of 8,533 mother-child pairs, and the data were adjusted for receipt of antiretroviral therapy, maternal stage of disease, and infant birth weight. The investigators found that elective cesarean section decreased the risk of transmission by approximately 50%, with a transmission rate of 8.4% for women who underwent elective cesarean section versus...
Indications for Cesarean Section

Consensus guidelines recommend that women with viral loads above 1,000 copies/mL near term should undergo scheduled cesarean section at 38 completed weeks of gestation, prior to the onset of labor or the rupture of membranes.\(^6\) In addition, intravenous zidovudine should be started 3 hours prior to delivery and continued throughout delivery.\(^6\) For women with a near-term HIV RNA level less than 1,000 copies/mL, cesarean section probably does not significantly reduce the risk of HIV transmission, and thus most experts would not recommend scheduled cesarean section in that situation.\(^9\) If a near-term viral load has not been performed, decisions regarding cesarean section should be made based on the most recent HIV RNA level. Women taking antiretroviral therapy should remain on therapy through delivery and continue therapy after delivery if indicated for maternal purposes.

Timing of Planned Cesarean Section

For women scheduled to undergo cesarean section, most of the guidelines recommend that it take place at 38 completed weeks of gestation (determined by best clinical estimate), prior to the onset of labor or the rupture of membranes.\(^9,65\) Majority of the guidelines recommend performing a scheduled cesarean section delivery at 38 completed weeks of gestation, as opposed to the 39 weeks recommended for persons not infected with HIV, because of the substantially higher risk of entering labor or rupturing membranes after 38 weeks of completed gestation. On the other hand, performing a cesarean delivery at 38 versus 39 completed weeks of gestation confers a small increased risk of infant respiratory distress possibly requiring mechanical ventilation. Although it would be ideal to know the status of the fetal lung maturity prior to cesarean section, it is recommended to avoid amniocentesis, primarily to avoid fetal exposure to maternal blood.\(^6\)

Scheduled Cesarean Section, but Woman Presents in Labor

When a woman is scheduled to undergo cesarean section, but presents early in labor (or shortly after rupture of membranes), the benefit of cesarean section is unknown and decisions regarding the approach to delivery should be individualized. If the woman has minimal cervical dilatation and is likely to have extended labor, one option is to immediately give the loading dose of intravenous zidovudine and then proceed to cesarean section.\(^9\) Alternatively, one could immediately give the loading dose of intravenous zidovudine and then start oxytocin to expedite delivery with vaginal delivery performed as long as rapid labor ensues.\(^9\) For any vaginal delivery, the duration of ruptured membranes should be as short as possible, given the increased risk of HIV transmission with longer duration of membrane rupture. Rupture of membranes for longer than 4 hours doubles the risk of HIV transmission.\(^6,66,68\) For any vaginal delivery, the clinician should, if possible, avoid using scalp electrodes or other invasive monitoring devices, forceps, or the vacuum extractor.

Complications of Cesarean Section

Although limited data exist regarding maternal morbidity following cesarean section in HIV-infected women, several studies have suggested that HIV-infected women who undergo cesarean section have higher complication rates than women who deliver vaginally.\(^7,71\) Post-delivery complications most frequently consist of hemorrhage, postpartum fever, cesarean wound infection, endometritis, urinary tract infection and sepsis.\(^6,67,70,72\) Among HIV-infected women who deliver via cesarean, those with CD4 counts less than 200 cells/mm\(^3\) have a greater rate of complications.\(^70\) Because of the increase in infectious complications, the consensus guidelines recommend that following cord clamping with a cesarean delivery, the mother should receive prophylactic antibiotics, which reduces the risk of postpartum maternal infection.\(^9\)

SUMMARY

- A woman with HIV can transmit the virus to her infant either during pregnancy, labor or after childbirth via breastfeeding. Several factors are associated with a higher risk of transmission, including the maternal viral load and CD4 cell count.
• Without treatment, the chance of transmitting HIV from a mother to a baby is somewhere between 12% and 25% in the developed world, and between 20% and 45% in resource-limited settings. It is greatly influenced by whether the child is breastfed.

• In 1994, a controlled clinical trial demonstrated that treatment with AZT or zidovudine during pregnancy, delivery and to the infant after birth can reduce the risk of mother-to-child transmission of HIV by two-thirds. Subsequent studies reported that other treatment courses with AZT and other antiretroviral drugs could also reduce the likelihood of infection of the infant.

• One trial in Uganda demonstrated significant reductions in HIV transmission simply by giving a single dose of nevirapine to the mother at the start of labor and to her infant within 72 hours of childbirth. This simple and inexpensive approach allowed resource-limited countries to design and implement programs for the prevention of mother-to-child transmission (PMTCT). However, there are concerns that this strategy could lead to the development of nevirapine resistance in mothers and infants who become infected. This could limit their future treatment options.

• In the developed world, widespread use of antiretroviral therapy during pregnancy has been associated with a dramatically reduced incidence of mother-to-child transmission among women with HIV who do not breastfeed.

• The long-term safety of exposure to antiretroviral drugs in the womb and early in life is not known and is a risk that must be balanced against the benefit of reduced HIV transmission. There is little evidence that antiretroviral drugs cause a significant risk of serious abnormalities.

• Planned caesarean delivery reduces mother-to-baby transmission in women who do not take any treatment, and in women who receive AZT in pregnancy. However, it is not clear whether this mode of delivery is advisable for pregnant women whose viral load is suppressed by antiretroviral therapy.

• The management of any HIV-positive pregnant woman requires a careful consideration of the balance between the mother’s health needs, locally available treatment options, the need to reduce transmission and the adverse effects of antiretroviral therapy. Recommended treatment options vary by country and local resources.

• After birth, breastfeeding poses an ongoing transmission risk, and additional effective measures are needed to reduce transmission through this route.

• Most women in the developed world choose to feed their child with infant formula. However, in resource-poor settings, replacement feeding is not always a viable option because of the lack of safe water or a reliable supply of infant formula. Even when formula is available, the choice is not a simple one in areas where malnutrition and childhood illness are common, because infants who are not breastfed are more likely to die from other causes.

• Two studies have shown that mixed breast and formula or solid feeding carries a higher risk of HIV transmission than exclusive breastfeeding. Exclusive breastfeeding and early weaning are recommended.

• Ongoing studies are evaluating the potential role for antiretroviral treatment to prevent HIV transmission to breastfed infants.

• Though PMTCT appears to have become more complicated, it continues to be the most effective approach in HIV infection in pregnancy.

INTRODUCTION
Approximately 10% of all human pregnancies end in spontaneous abortions. In the majority of such cases the etiology remains unknown, but anticardiolipin antibodies (aCL) are gaining recognition as potential causes of recurrent miscarriage. Repeated pregnancy loss and being childless is not only a gynecological problem but also a social stigma, in the Indian scenario. The price of motherhood is high and helpless couples seek to tide over this major crisis in their homes and society. Multiple studies have demonstrated the high incidence of psychological problems like low self-esteem, security and self-confidence among the childless couples. Women in particular suffer the deleterious consequences due to the common misconception that it is always the shortcoming of the female. This takes huge toll on the woman in terms of loss of self-esteem, grief, and feelings of failure. Recurrent abortion is a heterogeneous condition which is extremely traumatic emotionally as well as physically. Despite thorough investigation according to various clinical protocols, the underlying etiology remains obscure in the majority of patients, and obstetricians are facing a challenge to determine the cause of these unexplained abortions. Recently, the presence of IgG-aCL has been associated with approximately 40% of such cases. As the technology advances, physicians today have the ability to achieve successful outcome in many couples who would have been totally incapable doing so only a few years ago.

The aim of this chapter is to highlight the importance of different causes of recurrent spontaneous abortions (RSA) and the outcome of such treatment protocols and counseling the patients in case of adverse result. The ultimate aim is to improve the take home baby rate. The discussion can be exhaustive and hence for the purpose of this chapter we are discussing the causes and the management of recurrent first trimester abortions only. The management of second trimester losses is being handled in another part of this book. The literature review is by the Medline (1966 to November 2005), the Cochrane Library (2005, Issue 4), and the Cochrane Pregnancy and Childbirth Group (The Cochrane Library 2005, Issue 2) databases, and journal search, for the different options available for the same, and highlights the current modes of treatment.

INCIDENCE
Sixteen percent of all clinically recognized pregnancies result in a miscarriage; however, 80% of all conceptions are not even recognized as pregnancies due to early biochemical losses. The risk of abortion rises to 55% after three consecutive spontaneous abortions¹ (Box 1).

DEFINITION

Recurrent pregnancy losses can be divided as follows:
- Recurrent spontaneous abortions (before viability)
- First trimester and second trimester
- Recurrent bad obstetric outcomes (after viability)
- Late second trimester and third trimester

Classical definition: It is classically defined as three or more consecutive pregnancy losses at 20 weeks or less or with fetal weight less than 500 g. Most women with recurrent miscarriage have embryonic or early fetal loss, and the minority of losses are after 14 weeks. Although the definition includes three or more miscarriages, many agree that evaluation should at least be considered following two consecutive losses:
1. Primary recurrent miscarriage—no successful pregnancies
2. Secondary recurrent miscarriage—one prior livebirth as the latter group does not reach a risk of subsequent loss of 32% until after three miscarriages. Thus, it is reasonable to delay evaluation of secondary recurrent loss until three consecutive losses.

Most of us in clinical practice would start basic investigation after two losses and aggressive management after three losses. This is also due to the fact that, spontaneous chance of the third pregnancy succeeding after two losses is not unknown but risk of a third abortion is nearly 38%.\(^1,2\) Research in RSA is associated with numerous problems which are listed in Box 2.

ETIOLOGY OF RECURRENT SPONTANEOUS ABORTIONS

We can divide the causes of RSA into two main categories. Those which have known causes and the unknown (Table 1, Box 3). More than 50% of RSA patients fall into the latter group. With more understanding of the immune system and the role of antibodies in governing the pregnancy, antiphospholipids seem to have role to play in the etiology of RSA.\(^3\) They can also be divided into doubtful causes and possible causes. The important factor to understand is that it is necessary to prove the same cause in every pregnancy loss before we label a factor as the etiology behind the RSA. Having a positive test in one pregnancy is not to be included as the causes of RSA (Table 2).

### Box 2: Problems of research in recurrent spontaneous abortions
- The cause of individual abortion may be different
- More than one factor may exist
- Thorough investigation often fails to reveal a cause

### Table 1: Etiology of recurrent spontaneous abortions\(^1,2\)

**Doubtful causes of RSA**

- **Endocrine and metabolic disease:**
  - Untreated adrenal hyperplasia
  - Diabetes mellitus
- **Exogenous causes:**
  - Environmental factors, alcohol, street drugs, anesthesia, gases, etc.
- **TORCH infections**

**Possible causes of RSA**

- **Fetal abnormalities of genetic origin:**
  - Parental chromosomal rearrangement, aneuploidy, previous abnormality, chance, molecular mutations
- **Uterine anatomical defects:**
  - Body: Fibroids, septum, bicornuate uterus, etc.
  - Cervix: Incompetent internal orifice
- **Immunological:**
  - SLE, antiphospholipid antibodies, alloimmune factors, NK cells
- **Maternal age (Table 2)**
- **Hormonal:**
  - Corpus luteum deficiency (LPD), PCOS, Hypo/Hyperthyroidism
- **General disease:**
  - Wilson’s disease, renal dysfunction, chronic essential HT, etc.

**Abbreviations:** HT, hypertension; SLE, systemic lupus erythematosus; PCOS, polycystic ovary syndrome; LPD, luteal phase deficiencies; NK, natural killer

MANAGEMENT OF A PATIENT WITH RECURRENT SPONTANEOUS ABORTIONS

Recurrent abortion is a heterogeneous condition which is extremely traumatic emotionally as well as physically. Despite thorough investigation according to various clinical protocols (Box 4), the underlying etiology remains obscure in the majority of patients, and obstetricians are facing a challenge to determine the cause of these unexplained abortions.

Whenever the cause is found, the treatment remains treatment of the cause. Since more than 50% of the patients of RSA have no cause, the treatment remains empirical to a large extent. Recent evidence seems to suggest that the so called unknown etiologies may have an immunological basis (Figs 1A and B) and hence immune-modulation and prevention of thrombotic activity, forms the mainstay of management in known and unknown cases. Most often by default, the patients are advised bed rest in the hope of improving the uterine circulation. However, there is no obvious evidence that bed rest works, but is still commonly recommended. Some observational studies have suggested that TLC (Tender Loving Care) seems to be more effective as it instills confidence in the patient that there is someone who cares and is doing their utmost to help them. Once again, there is no evidence to support this. Tocolytic drugs have no role in the first trimester and should not be recommended for RSA.

Progesterone Support

It is a well-known fact, that luteal phase insufficiency can result or present as RSAs. The difficulty is in establishing the diagnosis. The gold standard is an endometrial biopsy, but with availability of serum markers, this invasive test is hardly resorted to. In the absence of any factor, the patients are given progesterone support till the placenta takes over luteal function. There are some early studies suggesting that there is no role for progesterone once the pregnancy test is positive and recommend stopping progesterone once beta-human chorionic gonadotropin is positive. Some studies suggest stopping progesterone once the fetal heart is demonstrated on ultrasound. However, most continue giving progesterone till the end of first trimester.

What is important to understand is that progesterone is the hormone which is responsible for the immune cascade of pregnancy and hence is called as an immunomodulator. How this precise mechanism works is unclear, but progesterone does help. It should be given in the dose of 600–800 mg per day either vaginally or orally. The vaginal route is preferred as it is locally administered and hence the bioavailability is
better. Injectable progesterone has good blood levels but local bioavailability is lesser than the local route. Progesterone can be given in the form of 8% vaginal gel also.8,9

POLYCYSTIC OVARY SYNDROME CAUSING RECURRENT PREGNANCY LOSSES

Rai et al.10 suggest that there is need to search for a specific endocrine abnormality that can divide women with polycystic ovary syndrome (PCOS) into those with good pregnancy outcomes and those with poorer pregnancy outcomes, irrespective of the type of conception. Of all clinical pregnancies, about 15% end in a first trimester loss or miscarriage.11 While the cause for recurrent miscarriage is impossible to identify in many cases, the incidence of PCOS amongst women with recurrent miscarriage is high,9 with one study suggesting the ultrasound incidence of polycystic ovaries (PCO) as high as 82%.12 Several studies have shown a clear relationship between the raised serum luteinizing hormone (LH) often found in association with PCOS and early pregnancy loss. In their study, Glueck et al.13 have demonstrated that, plasminogen activator inhibitor activity is an independent risk factor for the high miscarriage rate during pregnancy in women with PCOS. They concluded that “PAI-Fx is a predominant, independent, significant, positive and reversible risk factor for miscarriage in women with PCOS.” This may help us in reaching successful pregnancies in future of these women.

Hyperinsulinemia and Insulin Resistance

The association between increased insulin resistance and polycystic ovaries is now well-recognized. Insulin resistance is defined as a reduced glucose response to a given amount of insulin. The reason for hyperinsulinemia is increased peripheral target tissue resistance, and a decreased hepatic insulin clearance. There are three categories of peripheral target tissue insulin resistance: (1) decrease insulin receptor number, (2) decreased insulin binding and (3) postreceptor failure. The measurement of the ratio of fasting glucose to fasting insulin if less than 4.5, is consistent with insulin resistance. Women with PCO have android obesity which is seen as a waist-hip ratio (WHR) of greater than 0.85, and many of them have increased body mass index (BMI).14,15

There are various studies13,16-18 which were conducted to examine the effect of metformin therapy on ovarian response in clomiphene-resistant PCOS patients. In almost all of them, the total gonadotropin doses, duration of therapy, and plasma estradiol in the metformin-study group were significantly lower and there was a higher pregnancy outcome, along with a decrease in hyperstimulation risk, cycle cancellations, and multiple pregnancy rates. Glueck et al.13,18 concluded that “metformin therapy throughout pregnancy in women with PCOS reduces the otherwise high rate of first-trimester spontaneous abortion seen among women not receiving metformin and does not appear to be teratogenic.”

Hyperandrogenemia

Raised serum levels of free testosterone and androstenedione and reduced levels of sex-hormone-binding globulin are found in association will PCOS.15,20 However, these changes have also been reported in women with recurrent miscarriage without other features of PCOS (raised LH or PCO by ultrasonography) and hence are of doubtful significance.21,22

It is clear that there is an association between PCOS and early pregnancy loss, and more so in women with hypersecretion of LH and hyperinsulinemia. It would appear that presence of raised early follicular LH levels, ultrasound diagnosis of PCOS, obesity, hyperinsulinemia, and hyperandrogenemia either single or in combination are associated with an increased risk of miscarriage.

GENETIC ABNORMALITIES

Most common causes of chromosomal problems are seen in the form of parental chromosomal rearrangements and/or aneuploidy. These can be because of a previous abnormality or a chance molecular mutation. The fact is that the incidence of finding chromosomal abnormalities is 3.6–6.1% as against 1.2% in the general population. These abnormalities can be a balanced translocation (Reciprocal or Robertsonian) or an inversion which gives rise to unbalanced translocation.1,2,4

The management options are limited and are as follows:

• Genetic counseling against risks
• Preimplantation genetic diagnosis (in known cases of abnormality)
• Donor eggs or sperm
• Genetic evaluation of fetus by chorion villus biopsy or amniocentesis.

ANTIPHOSPHOLIPID ANTIBODY (APLA) SYNDROME

Antiphospholipid antibodies were first described in 1906 in a study by Wassermann et al.23 among patients with positive serologic test results for syphilis. Antiphospholipid antibodies are a heterogeneous group of autoantibodies directed against phospholipid-binding proteins. Antiphospholipid antibodies can be broadly categorized into those antibodies that prolong phospholipid-dependent coagulation assays, known as lupus anticoagulants (LA), or aCL, which target a molecular congener of cardiolipin (a bovine cardiac protein). The presence of these antibodies in patients with arterial or venous thrombosis or pregnancy morbidity comprises the antiphospholipid antibody syndrome (APLAS), when this occurs in association with other conditions, such as systemic
lupus erythematosus (SLE). Antiphospholipid antibodies are also found in patients with infections such as human immunodeficiency virus and may develop during therapy with medications such as chlorpromazine.24,25

The presence of antiphospholipid antibodies in serum has been associated with the antiphospholipid-antibody syndrome, which is characterized by arterial and venous thrombosis or recurrent pregnancy loss attributed to placental thrombosis.23,25 The pathogenic mechanisms of this disorder are unknown. Remarkably, "lupus anticoagulants"—antibodies against anionic phospholipids or associated proteins, which inhibit phospholipid-dependent blood coagulation—are frequently found in patients with this disorder. Yet, paradoxically, these anticoagulants are associated with thrombotic manifestations and not with bleeding disorders.

Treatment of antiphospholipid antibodies is problematic because of a lack of laboratory standardization, limited data on their natural history, and a lack of randomized treatment trials. Depending on the assay, antiphospholipid antibodies are reported in up to 10% of healthy individuals and in 30–50% of patients with SLE.26,27

**Laboratory Detection of Antiphospholipid Antibodies**

Laboratory testing for antiphospholipid antibodies is complicated because there is certainty about their antigen target. Both LA and aCL may demonstrate specificity for β₂-glycoprotein I,28 but many other antigenic targets have been described including prothrombin and annexin V.29,30

**Lupus Anticoagulants**

Lupus anticoagulants, also referred to as nonspecific inhibitors, are antibodies that block phospholipid surfaces important for coagulation. They reduce the coagulant potential of the plasma and prolong the clotting time in coagulation tests based on the activated partial thromboplastin time. Failure of the prolonged clotting time to correct after a 1:1 mix with normal platelet-free plasma and correction of the clotting time after addition of excess phospholipids confirms the presence of LA. Anticoagulant therapy may interfere with the detection of LA.28,31

**Anticardiolipin Antibodies**

Anticardiolipin antibodies share a common in vitro binding affinity for cardiolipin and can be detected using enzyme-linked immunosorbent assays. The immunoglobulin isotype may be IgG, IgM, or IgA. Enzyme-linked immunosorbent assay tests for aCL are poorly standardized and aCL testing has shown poor concordance between laboratories. aCL are reported as a titer specific to the isotype (IgG, IgM, or IgA phospholipid antibody titer), but because the accuracy and reliability of assays are limited, consensus guidelines recommend semiquantitative reporting of results (low, medium, or high titer).29,31

**Anti-β₂-Glycoprotein I Antibodies**

Anti-β₂-glycoprotein I antibodies32 are currently not included in the Sapporo criteria but may be incorporated in future updates. The laboratory assay for these antibodies is not standardized, making comparison between studies difficult.32,33 The clinical relevance of anti-β₂-glycoprotein I antibodies also is uncertain, although there is some evidence that these antibodies are more specific for APS.

**Diagnostic Criteria for Antiphospholipid Antibody Syndrome**

Consensus-derived diagnostic criteria formulated by the Sapporo international workshop require repeated measurement to establish a diagnosis of APS.34 APS is present in patients when there is at least one clinical and one laboratory criterion.

**Clinical Criteria**

- Confirmed arterial, venous, or small-vessel thrombosis
- Pregnancy morbidity consisting of recurrent fetal loss before the tenth week of gestation
- One or more unexplained fetal death at or beyond the tenth week of gestation
- Premature birth due to placental insufficiency, eclampsia, or pre-eclampsia

**Laboratory Criteria**

- Medium or high titer IgG or IgM aCL
- The presence of LA on two or more occasions at least 6 weeks apart

**Association of Antiphospholipid: Antibodies and Thrombosis**

In a general obstetric population, the prevalence of LA was 0.3% and the prevalence of aCL was 2.2–9.1%, which was similar to that observed among patients who are not pregnant (5.6%).29,30 Persistently positive antiphospholipid antibodies are unusual in healthy individuals (< 2% of healthy blood donors initially found to have aCL still had increased levels 9 months later).28 In comparison, the prevalence of antiphospholipid antibodies appears to be higher, in the range of 4–21%, among patients presenting with thrombosis or recurrent pregnancy.31,33 The increased prevalence of antiphospholipid antibodies among patients with thrombosis suggests an association between antiphospholipid antibodies and thrombosis, and the increasing risk of thrombosis...
among those patients with increasing antibody titers further strengthens the evidence that the association is causal. However, there remains controversy about the true nature of this relationship, which may also be confounded by the presence of unmeasured LA. The association between antiphospholipid antibodies and thrombosis is stronger with LA than with aCL. In a meta-analysis of 25 studies involving more than 7,000 patients, the mean odds ratio for thrombosis was 1.6 for aCL and 11.0 for LA.\textsuperscript{2,33,36}

Thrombosis is presumed to cause many of the pregnancy complications associated with APS. In women without SLE, a retrospective review of more than 13,000 patients found a prevalence of antiphospholipid antibodies of 20% among women with recurrent fetal loss compared with 5% in healthy women.\textsuperscript{36} The association between antiphospholipid antibodies and fetal loss is strongest for loss occurring after 10 weeks.\textsuperscript{37,38}

**Antithrombotic Treatment of Antiphospholipid Antibody Syndrome in Pregnancy**

The optimal treatment of pregnant women with antiphospholipid antibodies and one or more fetal losses after 10 weeks’ gestation without thrombosis is controversial. A systematic review\textsuperscript{38,39} of 13 randomized and quasi-randomized trials involving 849 pregnant women with a history of pregnancy loss and antiphospholipid antibodies found that combination therapy with unfractionated heparin (5,000 units subcutaneously twice daily) and aspirin (75–81 mg/day) significantly reduced pregnancy loss compared with aspirin alone [relative risk (RR), 0.46; 95% confidence interval (CI), 0.29–0.71]. However, this particular comparison was examined in only two trials involving 140 patients. The combination of low-molecular-weight heparin (5,000 units subcutaneously daily) and aspirin (75 mg/day) compared with aspirin alone did not significantly reduce pregnancy loss (RR, 0.78; 95% CI, 0.39–1.57), based on one trial of 98 patients.\textsuperscript{40,41} Aspirin (50–81 mg/day) compared with placebo or usual care did not reduce the rate of pregnancy loss in three trials (RR, 1.05; 95% CI, 0.66–1.68).\textsuperscript{42,43} Low doses of subcutaneous unfractionated heparin (5,000 units twice daily) appear to be as effective as high-dose heparin (10,000 units twice daily) (RR, 0.83; 95% CI, 0.29–2.38).\textsuperscript{44,45}

**Patients with Fetal Loss but No Prior Thrombosis**

The risk of thrombosis among women with antiphospholipid antibodies and fetal loss may be increased, based on the results of a retrospective study comparing aspirin with no prophylaxis in 65 nonpregnant women with antiphospholipid antibodies and a history of pregnancy loss. During a mean (standard deviation) duration of 8.1 (3.5) years, 20 (59%) of 34 patients who were not treated experienced venous or arterial thrombosis.\textsuperscript{46–49}

Consensus recommendations suggest that women with antiphospholipid antibodies and a history of two or more early pregnancy losses or one or more late pregnancy losses who have no prior history of thrombosis receive treatment with combination aspirin and heparin (unfractionated or low-molecular-weight) during pregnancy. Aspirin (81 mg/day) should be started with attempted conception and heparin (5,000–10,000 units every 12 hours) or low-molecular-weight heparin in prophylactic doses (enoxaparin, 1 mg/kg or 40–80 mg; dalteparin, 5,000 units; or nadroparin, 3,800 units, all administered once daily) should be started when a viable intrauterine pregnancy is documented and continued until late in the third trimester.\textsuperscript{40,44,46–53}

**Controversies in Antithrombotic: Prophylaxis in Antiphospholipid Antibody Syndrome**

The treatment of patients who are incidentally found to have an antiphospholipid antibody and have no prior thrombosis has not been adequately studied, except in patients with SLE. Consensus opinion suggests low-dose aspirin (81 mg/day) may be considered for asymptomatic patients who are not pregnant.\textsuperscript{53–55}

Researchers have suggested that the evidence of a potentially important prothrombotic effect of these antibodies—areduction in the quantity of the potent anticoagulant protein annexin V on the surface of placental trophoblasts and vascular endothelial cells. This is associated with an increase in the rate of coagulation at the cell surface. It stands in contrast to the “lupus anticoagulant” phenomenon observed with routine phospholipid-dependent coagulation assays. The 54-kd serum glycoprotein $\beta_2$-glycoprotein I ($\beta_2$-GPI, also known as apolipoprotein H) and other phospholipid-binding proteins appear to serve as cofactors in the recognition of their putative antigens by antiphospholipid antibodies.

**Obstetrical Considerations**

Women with antiphospholipid antibodies have an unusually high proportion of pregnancy losses within the fetal period (10 or more weeks of gestation). In contrast, in unselected women with sporadic or recurrent miscarriage, pregnancy losses occur more commonly in the pre-embryonic period (less than 6 weeks of gestation) or the embryonic period (6–9 weeks of gestation). Pregnancies in women who are positive for antiphospholipid antibodies can also be complicated by premature delivery due to pregnancy-associated hypertensive disease and uteroplacental insufficiency. Adverse pregnancy outcomes in women with the antiphospholipid syndrome may result from poor placental perfusion due to localized thrombosis, perhaps through interference with trophoblastic annexin V that is mediated by antiphospholipid antibodies. Antiphospholipid antibodies may also impair trophoblastic invasion and hormone production, thereby promoting not only
pre-embryonic and embryonic loss but also fetal loss and uteroplacental insufficiency.\textsuperscript{40,56-58}

Treatement has evolved considerably. Early enthusiasm for glucocorticoids waned when a small, randomized trial found heparin administered to pregnant women to be as effective as prednisone. Recently, two prospective trials showed that heparin plus low-dose aspirin is more effective than aspirin alone for achieving livebirths among women with antiphospholipid antibodies and predominantly pre-embryonic and embryonic pregnancy loss. A third prospective trial of women who were positive for antiphospholipid antibodies and had repeated pregnancy loss but no history of thrombosis or SLE found similar rates of livebirths (approximately 80%) with the use of either low-dose aspirin or placebo, suggesting that treatment may be unnecessary in some women. Although intravenous immune globulin has been used to treat some autoimmune conditions in pregnancy, a randomized, controlled study found no benefit of intravenous immune globulin as compared with heparin and aspirin in reducing adverse obstetrical outcomes in women with the antiphospholipid syndrome.\textsuperscript{54,57}

Concern about patient selection notwithstanding, most experts recognize the antiphospholipid syndrome as a proven, treatable cause of recurrent pregnancy loss. Currently, heparin administered to pregnant women after ultrasonographic demonstration of a live embryo is the treatment of choice, although the dose is debated. Women with recurrent pre-embryonic and embryonic pregnancy loss and no history of thromboembolism may be treated with 5,000 U of heparin twice daily, but experts recommend higher doses, sufficient to produce full anticoagulation, for women with prior thromboembolism. The optimal treatment for women with pregnancy loss during the fetal period but no history of thromboembolism is controversial because of the potential risk of maternal thromboembolism. Generous thromboprophylaxis (15,000–20,000 U of heparin per day) or adjusted thromboprophylaxis (15,000–20,000 U of heparin per day) is favored by some, but there are no properly designed studies for guidance. Experts agree that low-molecular-weight heparin may be substituted for standard heparin in the treatment of pregnant women with the antiphospholipid syndrome.\textsuperscript{56,58-62}

\section*{CONCLUSION}

Recurrent abortion is a heterogeneous condition which is extremely traumatic emotionally as well as physically. Despite thorough investigation according to various clinical protocols, the underlying etiology remains obscure in the majority of patients, and obstetricians are facing a challenge to determine the cause of these unexplained abortions.

Progesterone supplementation is the recommended therapy for luteal insufficiency. Metformin may have a role in PCOS-induced recurrent pregnancy loss. Majority of research now is directed toward immunological causes and a lot of questions still remain unanswered. Since initial reports of an association between aCL and thrombosis and fetal death, much of the research has focused on the pathogenesis and clinical features of APS. The results of these studies indicate that patients with antiphospholipid antibodies and venous thrombosis should be treated with long-term (potentially indefinite) anticoagulation administered to achieve an INR of 2.0–3.0, when not pregnant. But, during pregnancy the treatment of choice is low dose aspirin and low molecular weight heparin. Prospective studies addressing the issue of primary antithrombotic prophylaxis in asymptomatic patients with antiphospholipid antibodies are in progress. The role of immunoglobulins is not yet fully established. These and other well-designed prospective studies are required to complete the understanding of the optimal treatment of patients with antiphospholipid antibodies and APS and recurrent pregnancy loss.

Medical Disorders in Pregnancy

SECTION 3

Fetus as a Patient
INTRODUCTION

The objective of prenatal diagnostic techniques is to provide physical, genetic, physiological and biochemical information about the fetus for reassurance of normalcy and gauging the severity of abnormality.

Prenatal genetic diagnosis was introduced as a formal test in early seventies.¹

The availability of first trimester prenatal diagnosis and the advent of presymptomatic diagnosis by deoxyribonucleic acid (DNA) analysis have created further opportunities to avoid disorders characterized by early death, severe disease or irreparable brain damage.

COMMONLY USED GENETIC TESTS FOR PRENATAL DIAGNOSIS

Biochemical Testing

Direct analysis of proteins and other metabolites that are abnormal in certain genetic conditions. For example, tyrosinemia type 1 involves measurement of succinyl acetone in amniotic fluid.²

Deoxyribonucleic Acid Testing

The most commonly used DNA tests in the prenatal setting are β-thalassemia, hemophilia, Duchenne muscular dystrophy, etc. For monogenic disorders testing is often reserved for families at risk for the disorder. This usually requires prior diagnosis of an affected individual or carrier couple for autosomal recessive disorders. Molecular diagnosis should ideally be done before the pregnancy to define the precise mutation. In some cases, definitive testing may not be possible and linkage analysis may be required such as in a family of Duchenne muscular dystrophy in which no mutation has been identified. A linked marker is a sequence of DNA that lies near the gene of interest and shows individual variation in the DNA sequence, which allows the tracking of the chromosome carrying the affected gene. Using several markers as close to the gene site as possible, scope of error is minimized.³

Cytogenetic Testing

Cell culture: Cells are cultured and then harvested at the metaphase stage, at which time chromosomes are condensed and display their banded appearance. High-magnification light microscopy is used to look for abnormalities of chromosome number and structure.

Direct preparation: Direct preparation of genetic material, without culturing, is possible after chorionic villus sampling (CVS) because the cytotrophoblastic tissue has an extremely high mitotic rate. This permits a provisional interpretation to be provided in as little as 24–48 hours. This method also minimizes the risk of maternal cell contamination but suffers from poor quality banding.

Fluorescence in situ hybridization: The technique for fluorescent in situ hybridization (FISH) relies on the unique ability of a portion of single-stranded DNA, known as a probe, to hybridize (bond) with its complementary target DNA
sequence. The signal is directly visualized by fluorescent microscopy, and the presence or absence of specific DNA sequence is determined by observing whether a signal is present. Using commercially available probes and proper temperatures, the entire FISH process can be completed within 6–8 hours and as many as 5–7 probes may be used simultaneously. Trisomies and microdeletions like DiGeorge syndrome (22q11.2) can be diagnosed by FISH.4

## COMMON DIAGNOSTIC PROCEDURES DURING PREGNANCY (TABLE 1)
### NONINVASIVE SCREENINGS

#### First Trimester Aneuploidy Screen for Trisomy 21

Among the biochemical markers free beta-subunit of human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein A (PAPP-A) have been shown to be effective with detection rates in the range of 55–68%.5,6 Combining maternal serum biochemistry and nuchal translucency (NT) measurements in the first trimester is an effective screening protocol because the two modalities are independent and 89% detection with a 5% false-positive rate may be achieved.7

First trimester risk screening must be combined with the second trimester biochemical screening or possibly additional ultrasound screening to produce accurate risk estimates. Wald et al. have integrated information from selected first and second trimester markers to achieve detection rate of 94% for trisomy 21 at a 5% false-positive rate.8

#### Second Trimester Biochemical Screen at 15–21 Weeks for Trisomy 21

Alpha-fetoprotein (AFP), hCG and estriol together are used as a triple-marker combination with a detection rate of 61% at a 5% false-positive rate.9 Inhibin A has been added to the triple-marker test to form a “quadruple test” with an additional gain of 5–7%.10,11

**Trisomy 18:** An association of trisomy 18 has been found with a tendency toward decreased levels of all analytes that is low AFP, estriol hCG, progesterone, inhibin and PAPP-A levels.12,13

**Trisomy 13:** Second trimester screening with AFP, estriol, and hCG is probably not useful in detecting trisomy 13 and ultrasound alone can detect abnormalities in up to 90% of fetuses with trisomy 13 during the second trimester.14,15

#### Fetal Ultrasound for Detection of Anomalies at 18–20 Weeks

Ultrasound can frequently detect many abnormalities in fetuses. These may include structural defects, nonstructural findings, or sonographic markers of fetal aneuploidy.

Incorporation of ultrasound data improves the performance of second trimester serum screening, with aneuploidy (Table 2).16,17

#### Fetal Echocardiography: Optimum Time 20–24 Weeks

A fetal echocardiography should be offered to patients at risk for congenital heart disease such as history of a cardiac

Detection of cardiac anomaly will facilitate medical and surgical management after birth or termination before viability.18

Fetal Magnetic Resonance Imaging: 12 Weeks to Term

The greatest utility of fetal magnetic resonance imaging (MRI) is to clarify brain anomalies or injury when the ultrasonography (USG) has raised questions or has been inconclusive. Magnetic resonance findings not visualized by ultrasound include porencephaly, hemorrhage, partial or complete agenesis of the corpus callosum, cortical gyral abnormality, tethered cord, cortical clefts, midbrain abnormalities, partial or complete agenesis of the septi pellucidi, holoprosencephaly, cerebellar hypoplasia, subependymal and cortical tubers, vascular malformation, and vermian cysts. Abnormalities better defined by MRI than ultrasound include encephaloceles, arteriovenous malformations, distal neural tube defects and the mass effect of arachnoid cysts.19

Fetal magnetic resonance has been shown to be helpful in evaluation of neck and chest masses that potentially obstruct the airway.20

INVASIVE TECHNIQUES FOR OBTAINING FETAL SAMPLE

All patients should receive appropriate genetic counseling and should give informed consent before any prenatal invasive technique. Ultrasound examination should be performed to identify the number of fetuses, gestational ages, fetal positions, placental location(s) and presence of any fetal abnormalities. After any procedure, Rhesus (Rh) immunoglobulin (RhoGAM) should be given for patients who are Rh negative.

AMNIOCENTESIS

Genetic amniocentesis is most commonly performed during the second trimester but can be performed at any time up to delivery. It accounts for approximately 90% of prenatal tests. A needle is inserted through the woman’s abdominal wall into the amniotic sac around the fetus, under ultrasound guidance, and a sample is collected (Fig. 1). The cells in the amniotic fluid have been shed from the surface of the fetus and membranes. When performed during the second trimester, fetal karyotyping is usually performed with traditional cell culture. The main limitation of amniocentesis is the relatively advanced gestational age at which it is performed and the time delay due to the need to culture cells in the laboratory.

Indications

- Increased risk of fetal aneuploidy based on maternal age.
- Abnormal serum screen results.
- Prior medical history.
- Abnormal prenatal sonographic findings.
- Monitoring pregnancies at risk for Rh immunization.
- Evaluation of intrauterine infection in premature rupture of membranes (PPROM) or congenital infections.

Complications

- Amniocentesis failure: With the universal use of real-time sonographic guidance and the centralization of amniocentesis procedures at expert centers, the success rates of obtaining an adequate fluid sample are maximized.
- Pregnancy loss rate: We currently counsel all patients with singleton or multiple gestations of a 0.5–1.0% procedure-related loss rate.21–24
- Direct fetal injury: Direct fetal injury to the fetus from amniocentesis needle is an extremely uncommon event in the hands of an experienced operator using continuous sonographic visualization of the needle tip.
- Transient amniotic fluid leakage: The incidence of postamniocentesis fluid leakage was 1.7% for second trimester procedures. The postamniocentesis amniotic fluid leakage is associated with a significantly better overall prognosis from cases of spontaneous membrane rupture.25
- Mosaicism: Chromosomal mosaicism occurs in approximately 0.3% of amniocentesis cases. A diagnosis of true mosaicism is made when two cell populations with different karyotypes are found in at least two independent culture vessels. Pseudomosaicism is diagnosed when there
is only one cell or one region in a colony with abnormal karyotype, or when only one entire colony has an identical abnormal karyotype, or when multiple colonies within only one culture vessel show an identical abnormal karyotype. Depending on which definition is used; between 0.7% and 2.5% of all amniocentesis specimens will show pseudomosaicism. Excluding true mosaicism requires fetal blood sampling, with karyotype of cultured fetal lymphocytes. All fetuses with apparent mosaicism should also have a targeted fetal sonographic anatomy survey to aid in counseling. In cases of true mosaicism, the actual phenotype of the child is difficult to predict. After birth, the placenta should be sent for careful cytogenetic analysis.

Amniocentesis performed before 13 weeks or at 6 or 7 weeks is commonly referred to as early amniocentesis (EA). There is increased technical difficulty and complications associated with EA and so is no longer recommended.25

**CHORIONIC VILLOUS SAMPLING**

Chorionic villous sampling is a reasonable alternative to amniocentesis for first trimester diagnosis.26

**Indications**

Indications for doing CVS include cytogenetics testing, biochemical testing, polymerase chain reaction (PCR) for single gene disorder and fetal infection testing.

**Technique**

Chorionic villi can be obtained by the transcervical method or the transabdominal approach (Figs 2A and B). Transcervical sample is obtained with either a biopsy forceps or an aspiration catheter. Transabdominal CVS may be performed with either a needle-guide attachment or the free hand technique. The transabdominal approach generally uses a sterile single-use 20-guage spinal needle. The tip of the needle is then directed into the chorion frondosum parallel to the chorionic plate, slowly moving backward and forward four or five times while suctioning with the syringe.

After aspiration, the contents of the syringe and catheter or needle are flushed into a petri dish containing additional nutrient medium and the sample is carefully examined to confirm the presence of at least 10–30 mg of tissue. Patients should be advised that it is quite common to expect some light vaginal spotting especially after transcervical procedure, during the first 24 hours following the procedure.

**Complications**

**Chorionic villus sampling failure:** When performed by a skilled team, it is very unusual to fail to obtain adequate villus sample.

**Pregnancy loss:** Pregnancy loss for CVS compared with second trimester amniocentesis is between 0.5% and 1.0% but is unlikely to be any greater than 2.7%.27

Controversy exists on whether the two approaches to CVS (transabdominal vs. transcervical) are equally safe. No significant differences between the two procedures in pregnancy loss rates has been observed.28

**Limb reduction defects:** Procedures before 10 weeks may be associated with limb reduction defects of approximately 1–2%.29

Chorionic villous sampling is not recommended prior to 10 weeks to minimize the effect of transverse digital defects.
CHAPTER

Prenatal Diagnosis and Therapeutic Procedures

177

Fig. 3: Fetal umbilical vein sampling

Confined placental mosaicism is seen in 1% of all CVS specimens.\(^{30}\)

**FETAL UMBILICAL VEIN SAMPLING**

Fetal umbilical vein sampling, also known as *percutaneous umbilical blood sampling* (PUBS), refers to the aspiration of fetal blood from the umbilical vein using continuous sonographic guidance (Fig. 3).

**Indications**

The indications for PUBS have decreased with advances in alternative methods of diagnosis. DNA technology increased the range of genetic diseases that can be diagnosed using chorionic villi or amniocytes, and the range of infectious diseases that can be diagnosed using amniotic fluid. Additionally, advances in sonographic technology have increased the options for noninvasive diagnosis of fetal anemia, a relatively common indication for PUBS.

The most common genetic indication for PUBS is *rapid fetal karyotyping*; fetal karyotype can generally be achieved from cultured fetal lymphocytes in 48 to 72 hours. PUBS may also be indicated when *chromosomal mosaicism* is diagnosed at CVS or amniocentesis.

Hematologic indications for PUBS include assessment of fetal hematocrit in pregnant women with *red cell isoimmunization* and assessment of fetal *platelet count* in pregnant women with platelet alloimmunization, being used less frequently in the contemporary management of immune thrombocytopenia (ITP) in pregnancy.

**Technique**

Local anesthesia and prophylactic antibodies may or may not be administered. Sonography should be performed to select the best target for sampling: the most commonly used site is the umbilical vein at its placental insertion, as the cord is relatively immobile in this area. If the placenta is posterior and the placental cord insertion site cannot be reached, it is reasonable to attempt PUBS from the place umbilical vein can be reached; occasionally a free loop of cord may be sampled, although this is technically more difficult as the mobility of the cord can make needle entry difficult. Rarely, it may be necessary to obtain fetal blood from the intrahepatic vein if no other site is accessible. Needle placement may be performed with either a free hand technique or a needle-guided attachment. A 22 gauge needle is used for a diagnostic procedure and a 20 gauge for intrauterine transfusion.

After sampling into a heparinized syringe, confirmation of fetal origin of the blood cells is done.

**Complications**

Complications of PUBS include failure to obtain fetal blood and fetal loss rates of 0.9–3.2%\(^{31,32}\). Other complications of the procedure noted included needle site bleeding, transient fetal bradycardia, chorioamnionitis and umbilical cord hematoma.

**EMBRYO-FETOSCOPY**

Embryoscopy and fetoscopy were developed in the 1970s. They were introduced as diagnostic tools to visualize external malformations of the fetuses in the first, second and third trimesters of pregnancy as well as to obtain fetal tissue for diagnostic purpose.\(^{33}\)

Diagnostic fetoscopy during the second and third trimester was abandoned in the late 1980s due to the invasive nature of the technique and the development of high-resolution ultrasound imaging. Recently, there has been renewed interest in embryo-fetoscopy due to the increasing use of ultrasound in the first trimester together with the development of new equipment, especially miniature fiberscopes,\(^{34}\) and the use of laser for treatment of twin-twin transfusion syndrome.\(^{35}\)

**REFERENCES**

INTRODUCTION

Congenital infections have been the subject of clinical and laboratory research since the great rubella pandemics of the 1940s. Maternal infection can lead to fetal infection by hematologic spread to the placenta and hence to the fetus. As a consequence of this route of infection (Table 1), the infection can be limited to the placenta or both placenta and fetus can be infected. The timing and extent of fetal infection following maternal infection can vary, depending on the type of infection, the gestational age at infection, and the immunologic status of the mother. Fetal infection results from viruses, bacteria and parasites such as *Toxoplasma gondii*. Up to 10% of pregnancies yearly are affected. The occurrence during pregnancy of rubella virus infection, once an important causative agent of congenital malformations, has substantially decreased, thanks to a general program of vaccination.

The spectrum of fetal involvement ranges from asymptomatic infection to long-term sequelae (depending on the gestational age at exposure, infecting agent, and infectious load), to intrauterine death.

Congenital infections can be the cause of diseases in the neonate and are sometimes responsible for severe handicaps.

Under specific circumstances, they can be prevented and treated. We intend to describe the presentation and diagnostic approach to these infections. We have selected eight of these for detailing: rubella, cytomegalovirus (CMV), varicella, toxoplasmosis, parvovirus, herpes simplex virus (HSV), hepatitis B, and human immunodeficiency virus (HIV) for their importance from a practical point of view. For many of the specific infections discussed, few data are available in the literature, and specific recommendations cannot be made.

PRESENTATION

Fetal infection may occur at any time during pregnancy. Infection may occur early in pregnancy causing an embryonic/fetal demise or obvious stigmata at birth, during the second or third trimester causing either intrauterine growth restriction (IUGR) or nonimmune hydrops (NIH) or during labor and delivery. In addition, the active immunological capacity of the fetus and newborn is compromised compared to that of older children or adults.

DIAGNOSTIC TECHNIQUES

Evidence of fetal infection relies on the identification of the organism or detection of its antigens or genome in fetal compartments (amniotic fluid, fetal blood, or ascitic fluid) or the detection of specific immunoglobulin (Ig) M antibodies targeted to the offending organism in the fetal blood or amniotic fluid. Identifying an infectious agent can sometimes take weeks, however. The production of specific IgM antibodies depends on the maturity of the fetal immune system and the immunogenicity of the specific infectious agent. Therefore, the detection of specific IgM antibodies is reliable evidence of fetal infection, but their absence
does not rule it out. Nonspecific evidence of fetal infection can also be obtained from fetal blood sampling—elevated total IgM antibodies, thrombocytopenia, eosinophilia, and elevated liver enzyme levels—and although not diagnostic, it increases the likelihood of fetal involvement in the presence of a documented recent maternal infection.

**Amniocentesis**

First performed by Bevis in 1952 to detect the presence of bilirubin derivatives in the amniotic fluid of fetuses at risk for immune hemolytic anemia, this technique is now routinely used to detect infections (culture, electron microscopy). The risk of fetal loss is low (< 0.5% with ultrasound guidance) and complications are rare.

**Cordocentesis**

This technique is now routined for the investigation of fetal infections since, in most cases, pure fetal blood is obtained (i.e. no cross-contamination by maternal blood). The blood obtained may be cultured for virus (or other infecting agents) or used for serologic studies to identify IgM-specific antibody. The risk to the fetus is low and fetal loss occurs in less than 2% of procedures.

**Culture Methods**

The gold standard of diagnosis of fetal infection relies on culture of blood or buffy coat, amniotic fluid or placenta. However, in most cases the culture results are either negative or equivocal. Further, concern over maternal contamination is common. Lastly, identification is generally slow and certain viruses (i.e. parvovirus) do not readily grow in standard culture systems.

**Serologic Methods**

These methods have traditionally been relied on for antenatal diagnosis since culture is often not helpful. IgM-specific antiviral antibodies are sought since IgM is not normally passed transplacentally. Its presence in umbilical cord blood is generally considered diagnostic.

Diagnostic sensitivity of both culture and serology is related to the viral or parasitic load. In practice, an infectious etiology is documented by viral culture or serologic methods in only 5–15% of fetuses with hydrops or isolated ascites, pleural or pericardial fluids, with no obvious cause identified by these methods in over 20% of affected fetuses. For these reasons, diagnostic methods other than serology and culture have been sought.

**Polymerase Chain Reaction**

Polymerase chain reaction (PCR) permits the rapid detection (in 1–3 days) of nucleic acid from viruses, parasites and bacteria. PCR is an automated in vitro repetitive reaction that uses a heat-stable deoxyribonucleic acid (DNA) polymerase to amplify a specified segment of DNA. The elegance of PCR lies in its simplicity and ability to amplify a single copy of the target fragment of DNA up to a million-fold in a matter of hours, thus allowing easy access to large quantities of DNA of interest for analysis. The greatest limitation of PCR is the need to know a short stretch of nucleotide (base) sequence flanking both ends of the desired segment of DNA to develop the primers necessary for the amplification.

**Diagnostic Approach**

Possible viral disease should be sought using a combination of methods concomitantly. These methods include culture, serology and PCR analysis. The specimens of choice include amniotic fluid, fetal blood or placenta. Other samples such as ascitic, pleural, or pericardial fluids are acceptable but appear to be slightly less sensitive. In cases of fetal demise, at risk fetal tissue (i.e. heart, lung, liver, brain) is a good source for study and may be evaluated whether the tissue is frozen (best), fixed in formalin (useful) or paraffin (least useful). PCR may also be used in cases where nonviral etiologies (i.e. toxoplasma, chlamydia, etc.) are under consideration.

**DETAILS OF INDIVIDUAL INFECTIONS**

**Rubella**

The syndrome of congenital rubella was first described in 1941 by an Australian ophthalmologist. The virus of rubella is among the most pathogenic agents that can affect an embryo or a fetus. The most frequently encountered injury is neurosensory deafness. Before vaccination became the rule, rubella was responsible for 16% of the cases of deafness of central origin. Many other injuries including cardiac malformations, (persistent ductus arteriosus, ventricular septal defect) as well as eye lesions (cataract, microphthalmia, glaucoma, retinopathy) can be associated with it. The lesions of the central nervous system (CNS), including microcephaly, encephalitis, or mental retardation, can be extremely serious. These malformations are generally associated with IUGR and a dysfunction of the hematopoietic system. Ten to fifteen percent of the rubella infections contracted during the first trimester result in spontaneous abortion.

**Risks to the Fetus**

The risk of fetal infections and malformations varies with the different stages of pregnancy. The incidence of vertical transmission (fetal infection rate) declines from 90% during the first trimester to 25% at the end of the second trimester, and then rises again to 95–100% during the last month of pregnancy.
It is more difficult to assess the risk of fetal malformation, but serious and multiple damage is the rule when the infection occurs before 11 weeks of gestation. During the early second trimester, the global percentage of malformations is about 35%. After the 17th week of pregnancy, no further severe damage is observed and the children only present with subclinical forms of congenital rubella. It is not possible, however, to evaluate the possible long-term effects on neuropsychiatric development.

**Prenatal Diagnosis and Subsequent Approach**

In utero, diagnosis includes fetal blood sampling by cordocentesis for measurement of fetal levels of rubella—specific IgM, reverse transcription PCR (RT-PCR) and virus isolation from maternal pharyngeal swabs and products conception. RT-PCR can detect presence of viral ribonucleic acid (RNA) even when the fetal rubella virus-specific IgM obtained by fetal blood sampling is negative.

The accuracy of amniotic fluid culture, assessment of fetal blood for specific IgM or use of PCR is low enough that counseling based on gestational age-related risk of congenital infection provides equally good information on the risk of severe disease.

No treatment other than abortion is available. Immunoglobulin therapy after exposure to rubella early in pregnancy does not prevent fetal infection or teratogenic effects. Its use can be considered only when a pregnant woman with exposure to rubella would not consider terminating the pregnancy under any circumstances. No antiviral treatment is yet available or tested. Prevention of maternal infection is the best therapy.

**Prevention**

*Prepregnancy*: Widespread vaccination of children and susceptible adults will prevent outbreaks of rubella, thus reducing the possibility of congenital rubella infection. All children should receive a single dose of live, attenuated rubella vaccine at around 15 months of age (in a trivalent preparation of measles, mumps and rubella strains). Antibody to rubella virus should be detectable for up to 16 years after vaccination. However, individuals with low levels of antibody after vaccination may be susceptible to viremia and clinical infection. Vaccination is also recommended for adults found susceptible by serological testing or who do not have documentation of vaccination after their first birthday.

The rubella vaccine is a live virus preparation and should not be administered to pregnant women for theoretic reasons. However, the Centers for Disease Control has monitored inadvertent rubella vaccinations during pregnancy between 1971 and 1989, collecting over 500 cases. No case of congenital rubella syndrome was documented due to vaccine, although virus was isolated from the conception in several cases. Thus, patients accidentally vaccinated during pregnancy or becoming pregnant shortly after vaccination should be counseled and reassured that fetal risks are negligible.

Passive immunization by injection of specific immunoglobulins can be performed in cases of exposure during pregnancy. It is obviously useless if it is administered once the rash has appeared. Patients treated in this way may sustain a subclinical infection, and their serological condition should, therefore, be checked regularly. However, there is no evidence that passive immunization prevents fetal infection or damage.

**Cytomegalovirus**

Cytomegalovirus is a DNA virus and a member of herpes family of viruses, with an incidence of varying congenital infection, from 0.2% to 2.2% of livebirth, depending on the populations studies. The contagiousness of CMV is relatively low and its transmission requires prolonged and close contact (sexual intercourse, oropharyngeal secretions or transfusion of blood products). The infection is most often asymptomatic during pregnancy, and in Europe, 45% of pregnant women are positive at the beginning of pregnancy in the higher income groups and 85% of those in lower income groups are seropositive.

Among women with immunity to CMV, about 0.5–1% have a recurrent infection during pregnancy. Pre-existing maternal antibodies to CMV seem to protect the fetus, however, and lessen the incidence and severity of the manifestations of congenital CMV infection.

**Risks to the Fetus**

The risk of primary infection during pregnancy for seronegative women ranges from 1% to 4%. In 40% of the cases, the virus will be transmitted to the fetus. Eighty-five to 90% of the infected infants of these are likely to develop sequelae, most commonly hearing loss. The other 10–15% of the infected infants have symptoms at birth14 including petechiae, thrombocytopenia, increased conjugated bilirubin, hepatosplenomegaly, chorioretinitis, microcephaly and intracerebral calcifications. Pass published the long-term follow-up of 34 children suffering from cytomegalic inclusions disease: 10 of them were dead at the age of 2 years (most had died at the age of 3 months), 16 had microcephaly and cerebral palsy was extremely frequent. Twelve of them had impaired hearing or vision and the intelligence quotient (IQ) of 10 of the 24 survivors was under 80.

The transplacental transmission of CMV does not depend on the time when the mother was infected. Fetal infection has been described after primary infection during the first, second and third trimesters of pregnancy but the risk of symptoms and sequelae seems to be notably higher when the infection occurs during the first 27 weeks. There may be recurrences and reinfections, and the risk of fetal infection, then is the same as with primary infections. In such cases,
however, the risk of fetal damage is very low, if one considers that in areas where all pregnant women are seropositive no handicaps caused by CMV are observed.18,19

Prenatal Diagnosis

Prenatal diagnosis is based on fetal blood sampling and amniocentesis at 20–23 weeks. The virus itself can be isolated in amniotic fluid or fetal blood with the former being more reliable. Amniotic fluid culture is superior to fetal IgM in diagnosing fetal infection. Other nonspecific signs of infection, such as thrombocytopenia, elevated gamma-glutamyl transpeptidase (γ-GTP) and total IgM may also be seen. On ultrasonographic examination, intrauterine CMV infection may present as ascites or generalized hydrops, ventriculomegaly, intracranial calcifications, increased bowel echodensity, and growth retardation. It can be assumed that infected fetuses with ultrasonographic signs or evidence of hematopoietic or hepatic disease have an extremely high probability of severe disease and sequelae, however, the absence of abnormal sonographic findings does not rule out infection in a fetus.

Prevention

Vaccination is not widely available and consists of a live-attenuated virus, which should not be administered during pregnancy. Passive immunization is not possible since exposure to the infection cannot be identified in most cases. Given the particularities of CMV infection and the lack of prophylaxis or treatment, routine screening of pregnant women does not seem to be justified. The only mode of transmission of the CMV that can be prevented by the obstetrician is infection resulting from transfusions. Any pregnant woman receiving blood transfusions during pregnancy should receive CMV-negative blood, whatever her serological status may be.

No effective fetal therapy is yet available. Ganciclovir has been administered into umbilical vein of the fetus at 27 weeks. Dosage of 10 mg/day for 5 days, 15 mg/day for 3 days and 20 mg/day for 4 days was found to decrease viral load in amniotic fluid. But, fetal bradycardia and demise remain serious threats. It may decrease viral shedding and reduce the risk of organ damage in cases of in utero infection. Before this is attempted larger trials evaluating, the clinical efficacy and safety in newborns will be necessary.

For all these reasons, CMV congenital infections will probably remain a major cause of handicap in years to come.

Varicella

Primary varicella is rarely an adult’s disease. Approximately 95% of pregnant women are immune. Its incidence can be estimated at one to five cases in 10,000 pregnancies. However, maternal morbidity and mortality is relatively high. Out of 118 cases described in the medical literature, 20% had pneumonia, 10% of which resulted in the mother’s death.15 But, it should be pointed out that only the most serious cases are described in the literature. Pregnant women with acute Varicella infection, requires close observation for evidence of severe illness and dissemination. The high-risk women may be given varicella zoster virus (VZV) immunoglobulin in the dose of 125 u/10 kg of body weight, IM. The use of varicella zoster immune globulin (VZIG) is not recommended in pregnancy. Acyclovir in the dose of 5–10 mg/kg IV 8 hourly for 7 days has no untoward maternal or fetal side effects.

Risks to the Fetus

The virus is seldom transmitted to the fetus (1–2% of the cases). The syndrome of congenital varicella consists of typical malformations, such as cutaneous scars, hypoplasia of the hands and feet, cerebral cortical atrophy, mental retardation with convulsions, eye lesions such as chorioretinitis or cataract and IUGR. The risk of congenital varicella syndrome seems to be limited to first and early second trimester infections. All the cases of congenital varicella syndrome described have followed infections occurring between the 7th and the 21st week of pregnancy.

The pathogenesis of the lesions observed in cases of congenital varicella is not clear. Higa20 hypothesized that these injuries are not caused by the direct action of the virus but could result from the occurrence of genuine intrauterine fetal shingles.

The immunity conferred by varicella is stable and further infections are practically nonexistent. The risk of maternal varicella zoster is probably negligible because viremia is less frequent and the fetus is protected by the presence of maternal antibodies.

Prenatal Diagnosis and Subsequent Approach

In view of the small risk observed, termination of pregnancy is not indicated in cases of maternal varicella. Prenatal diagnosis by fetal blood sampling may be justified considering the severe CNS lesions observed in cases of fetal infection. Maternal varicella near the time of delivery carries a risk of neonatal varicella. In such cases, the risk of fetal infection ranges from 25% to 30%. The severity of neonatal varicella depends on the time of maternal infection with respect to delivery and on the development of maternal IgG. Maternal varicella occurring from 5 days to 21 days before delivery and developing in the infant during the first 4 days of its life will have a variable outcome with a good prognosis. When it occurs 4 days before to 2 days after delivery, which means that the child will develop the disease 5–10 days after birth, the infection can be very severe, with a very high risk of morbidity or mortality. The difference between benign neonatal disease during the first 4 days of life and the more severe manifestations of neonatal varicella at 5–10 days of life can easily be accounted for. In the first case, the maternal
antibodies are present with a very high concentration in fetal blood and protect the infant, whereas in the second case, the concentration of maternal antibodies in fetal blood is too low to ensure adequate protection.

**Prevention**

Passive immunization is currently available and should be administered within 24–72 hours to seronegative pregnant patients who have been exposed to varicella.

Once the rash is present, immunoglobulins should only be used at term if delivery is anticipated within 4–5 days.

Acyclovir crosses placental barrier\(^1\) and has been proposed by some authors for varicella occurring near delivery.\(^2\) However, the fetal effects are unknown, thus it cannot be recommended early in pregnancy. There is no evidence, however, that VZIG, acyclovir, or interferon treatment can alter the course of intrauterine infection or prevent fetal infection.

**Toxoplasmosis**

Toxoplasmosis is a parasite disease caused by a protozoan, *Toxoplasma gondii*. The cat is the only natural host. However, the toxoplasma can infect many animals (including humans). Humans can be either directly infected from cat feces or indirectly by ingestion of undercooked meat from parasitized animals. Infection is frequent but most often asymptomatic, except in cases of immunodeficiency. For pregnant women, the consequences of infection may be serious if the parasite is transmitted to the fetus.

**Risks to the Fetus**

The risk of fetal infection is 7%,\(^3\) but it varies with the time of seroconversion and regularly increases from the beginning to the end of pregnancy. Transmission to the fetus results from placental infection and secondary passage into the fetal circulation. On the other hand, the earlier the fetus is infected, the more serious are the sequelae. Severe congenital toxoplasmosis is a rare but most dangerous form of the disease, especially when the fetus has been infected during the first trimester of pregnancy. It is characterized by multisystemic damage and causes, in particular, destruction of cerebral tissue often associated with cerebral ventricle dilatation. Later the gestational age at infection, less severe the fetal damage. Overall, 70% are born without obvious damage, 10% suffer only ocular manifestations, 20% have the classic appearance of the TORCH baby.

**Prenatal Diagnosis and Treatment**

Prenatal diagnosis is based on ultrasound examination, amniocentesis and fetal blood sampling.\(^4\) It can be performed as of 18–20 weeks of amenorrhea. The analysis of fetal blood allows the detection of indirect biological signs of infection, i.e. leukocytosis, eosinophilia, thrombocytopenia, elevated levels of total IgM and gamma-glutamyl transferase, and specific fetal IgM. Parasitological test includes inoculation of fetal blood and amniotic fluid into mice and fibroblast cultures. Hohlfeld et al. demonstrated that prenatal diagnosis of congenital infection based on a PCR test using amniotic fluid is the preferred diagnostic approach. A serologic diagnosis requires a careful interpretation of the results because some tests have different sensitivities at various stages of infection. It is important to rely on a reference laboratory where several tests can be done in parallel with evaluations of previous specimens. There is as yet no consensus on whether routine testing for toxoplasmosis in pregnancy is cost-effective.

According to the prenatal diagnosis, three different approaches may be proposed. If the fetus is not infected, the treatment with spiramycin should be continued in order to avoid later contamination from an infected placenta, and ultrasound examinations will suffice until delivery.

Spiramycin is an antibiotic whose activity in toxoplasmosis has been experimentally and clinically documented.\(^5\) Its tissue concentration in the placenta is excellent, and it passes through the fetoplacental barrier having been found in fetal blood sampled for prenatal diagnosis.\(^6\) When toxoplasmosis occurs during pregnancy, spiramycin reduces the risk of fetal infection by 60%.\(^7\) Its purpose is not to treat an already infected fetus but to prevent the parasite from passing into the fetal circulation. The lapse of time between maternal seroconversion and the onset of spiramycin therapy seems to be of importance, as a prolonged interval is more often associated with the presence of severe fetal lesions on prenatal diagnosis.\(^8\) A dose of 3 g/day is necessary to obtain adequate placental concentrations. This treatment involves no particular risk, with excellent tolerance even when it is administered over long periods of time. No hepatotoxicity has ever been reported nor any interference with other drugs.

If the fetus is infected following toxoplasmosis acquired during the first trimester or if the ultrasound reveals cerebral damage, termination of the pregnancy should be considered.

**Prevention**

It is most important to warn seronegative pregnant women about the precautions they should take (Table 2).\(^9\)

**Parvovirus**

Human parvovirus B19 is a DNA virus in the family *Paroviridae*.

The pathogenic effect of parvovirus, particularly B19, on the fetus has been recognized for less than 10 years. The classical maternal symptoms are the typical facial rash and arthralgias, which are not very specific and usually do not lead to prenatal diagnosis.

Most often, prenatal diagnosis is considered once fetal hydrops is diagnosed on ultrasound. This is a consequence...
of acute fetal anemia due to the direct effect of the virus on the red blood cell precursors. B19 develops only on erythroid precursors [burst forming unit-erythroid (BFU-E)] and results in acute anemia and fetal death in 10–30% of cases.\textsuperscript{30}

**Prenatal Diagnosis**

Prenatal diagnosis is easily performed on fetal blood, which demonstrates an aplastic anemia and the presence of the virus (electron microscopy or DNA analysis).

**Evolution of Pregnancy**

Most hydropic fetuses will die of cardiac failure if in utero treatment is not instituted. However, spontaneous in utero recoveries have been reported without any sequelae at birth. Correction of the anemia by fetal blood transfusion is the only available treatment.\textsuperscript{31} It is unclear whether in utero transfusion improves fetal outcome. Infants who survive the severe anemia with or without in utero transfusion appear to develop normally. There is no conclusive evidence that B19 infection is associated with anatomic abnormalities. The efficacy of maternal prophylactic immunoglobulin administration after exposure has not been determined yet, and its use is not recommended at this time. A vaccine is not available.

**Herpes Virus**

Prevalence of herpes in pregnancy is 1%. Most women have recurrent rather than primary infection. Women with genital HSV during the first half of pregnancy have a significantly increased incidence of spontaneous abortion and in the second half have an increased incidence of preterm delivery and direct transmission of HSV to the newborn. The direct contact of the neonate with the virus containing maternal secretions during passage through the birth canal is the main source of infection. This allows the virus to enter the infant via the eyes, upper respiratory tract, scalp and the umbilical cord thereby leading to systemic infections.

Brown and associates\textsuperscript{32} found the following vertical transmission rates at the time of vaginal delivery: 50% for women with primary disease at the time of delivery, 33% for those with nonprimary first-episode disease, and 0–3% for those with recurrent disease. Neonatal herpes is divided into three categories of disease: (1) localized disease involving the skin, eye, and/or mouth; (2) disease involving the CNS and (3) disseminated disease. Although most infected infants have localized disease, it may progress to encephalitis or disseminated disease. Morbidity and mortality of neonatal disease are directly related to the severity of the disease. Whitley and colleagues\textsuperscript{33} reported no mortality with localized disease, 15% mortality with CNS involvement and 57% mortality with disseminated disease.

**Diagnosis**

The diagnosis of herpes infection is generally made clinically based on the appearance of painful vesicular lesions and ulcers in various stages of progression. However, one-third of women do not have typically appearing lesions. Herpes can also be diagnosed from changes noted in Papanicolaou smears (multinucleated giant cells and intranuclear inclusion bodies), although the sensitivity is poor. Viral culture of open lesions remains one of the best methods of detecting infection, but it too has a significant false-negative rate. When performing a viral culture for HSV from lesions that are not ulcerated, the lesion should be unroofed and the fluid sampled. Culture results are usually available within 48–72 hours. Other techniques, such as PCR and hybridization methods, are increasingly available. Commercially, available serologic tests have little utility. These tests cannot reliably distinguish between HSV-1 and HSV-2. Serologic diagnosis of primary infection can only be made by documenting seroconversion from a negative to a positive IgM antibody titer. The presence of antibody titer in an initial specimen or the presence of a typical lesion is suggestive of nonprimary first-episode or recurrent disease.

**Prevention**

Women who at the time of admission in labor have overt vesicular lesions from primary or recurrent infections should undergo cesarean section regardless of time since rupture of membranes. Asymptomatic women should be examined for prodromal symptoms and vesicular lesions and if absent, then vaginal delivery may be conducted.\textsuperscript{34} Scott\textsuperscript{35} has answered various questions related to the use of acyclovir. The first issue, about fetal and neonatal safety, appears to be answered positively. With more than 1,812 infants reported to have been exposed to varying amounts and duration of maternal acyclovir suppression, there has not been any apparent, short-term adverse fetal or neonatal effect. Use of acyclovir in infants, even in those that are premature, is very well-tolerated, with a wide margin of safety. Acyclovir suppression actually decreases asymptomatic shedding.
along with decreasing clinical recurrences. Women who experience their first genital herpes outbreak while they are pregnant seem to benefit from acyclovir suppression, with both a decrease in the risk of clinical recurrences at delivery and a decreased need for cesarean delivery. Acyclovir’s efficacy in patients who have a history of genital herpes infections antedating their pregnancy is less clear. Acyclovir appears to be effective, at least in some cohorts, and is probably safe for the fetus.

Currently, there is no vaccine for the prevention of herpes infection. Valacyclovir and famciclovir are two newer antiviral agents that are effective and safe for the treatment of genital herpes.\textsuperscript{36}

**Hepatitis B and Others**

Hepatitis B virus is a member of the *Hepadnaviridae* family of DNA virus, first discovered in the 1960s. The main mode of transmission of hepatitis virus is blood and blood products. However, body fluids like saliva, vaginal secretions are also infective. Transplacental infection occurs in 5–8% of infants born to hepatitis B surface antigen (HbsAg) positive carriers. Newborns may be infected by swallowing-infected material during parturition. Mothers who are positive for hepatitis B “e” antigen (HbeAg) but negative for hepatitis B “e” antibody (HbeAb) carry a high risk of vertical transmission to her newborn.

**Fetal Risks**

If the fetus survives the acute maternal illness, without delivering prematurely, patient can be reassured that there are no teratogenic or congenital anomalies likely.

**Prevention**

A comprehensive prevention and treatment strategy\textsuperscript{37,38} has been developed by the Centers for Disease Control and Prevention, which includes screening of all pregnant women for the presence of HBV, the administration of hepatitis B immunoglobulin (HB Ig) at birth, and the administration of hepatitis B vaccine at birth, at 1 month of age, and at 6 months of age.

In case of exposure to hepatitis A, pregnant women should be given gamma globulin 0.02 mL/kg as early as possible. In case of exposure to hepatitis B, HB Ig and full course of hepatitis vaccination should be given. Universal vaccination of all neonates with hepatitis B vaccine is now recommended. Infants delivered to HbsAg seropositive mothers also should receive HB Ig and vaccination immediately after birth.

Hepatitis E is extremely rare in the United States and is quite similar to hepatitis A, although perinatal transmission does occur with hepatitis E. Hepatitis C and D, which are transmitted parenterally and by sexual contact, have been associated with vertical transmission. No immunoprophylaxis currently is available for neonates of mothers with hepatitis C or E virus. Immunization against hepatitis B is protective against vertical transmission of hepatitis D.

**Human Immunodeficiency Virus**

Pregnancy does not have an impact on the course of the HIV infection and nor does the infection adversely affect the course of the pregnancy, labor, puerperium and lactation. It is recommended that all pregnant women should be counseled and encouraged to be tested for HIV infection in order to know their infection status, both for their own health and to reduce the risk of perinatal HIV transmission. Prenatal diagnosis is not recommended as invasive procedures like fetal blood sampling may theoretically introduce the virus into a previously uninfected fetus. The magnitude of this risk is unknown. Furthermore, a fetus may become infected anytime after prenatal diagnosis because maternal viremia persists. Fetal HIV-1 infection does not seem to be associated with a substantially increased incidence of IUGR, prematurity, microcephaly, or dysmorphism.

**Prevention of Perinatal Human Immunodeficiency Virus Transmission**

The mainstay of the treatment of nonpregnant women with acquired immunodeficiency syndrome (AIDS), AIDS-related complex, or CD4+ cell counts of less than 200 × 10\textsuperscript{6} per liter rests on antiretroviral therapy with zidovudine and pneumocystis carinii pneumonia prophylaxis with the combination drug trimethoprim and sulfamethoxazole. Because of the lack of solid data on the fetal side effects and toxicities, the Public Health Service has avoided recommending therapies in pregnancy, but as there are no adverse fetal effects known to outweigh the maternal benefits of these therapies, they should not be withheld during pregnancy. Most obstetricians offer zidovudine treatment to pregnant women in advanced stages of disease, avoiding its use during the first trimester because of possible teratogenic risks.

Prevention of perinatal HIV transmission is possible by drug regimes and as suggested on the basis of a review of the Cochrane database of systematic reviews.\textsuperscript{39,40}

**Human Immunodeficiency Virus Infection: Diagnosis in the Newborn**

In utero, diagnosis is not possible. Fetus could be infected in the antepartum, intrapartum or postpartum period.

Many advances have been made in the area of neonatal HIV diagnosis.\textsuperscript{41} Commercially, available virologic assays are sensitive and specific for the early detection of HIV in perinatal infection.\textsuperscript{42,43} The timing of the transmission of HIV from mother to child (in utero, at the time of birth, or postnatally by breastfeeding) is a critical consideration in the appropriate diagnosis of infants. Several algorithms can
be used to define early infection and the potential timing of acquisition of infection that combine different assays and timing of specimens. The use of virologic assays, including HIV DNA PCR and HIV RNA detection methods and culture, can define and rule out infection in infants less than 6 weeks of age. A dried blood spot specimen is all that is needed for PCR, but these methods are expensive. Serologic diagnostic methods, including HIV enzyme-linked immunosorbent assay, immunofluorescence, and western blot assays, can be used to diagnose infants more than 18 months of age, when transplacental antibody has disappeared in uninfected HIV-exposed infants. The challenge of the early and accurate diagnosis of perinatally HIV-exposed infants is the use of new assays to detect different HIV subtype infections that are prevalent in developing countries. Rapid, simple, and inexpensive serologic and virologic assays are being developed for worldwide use.

Recent Trends in the Management of Recurrent Pregnancy Wastage

INTRODUCTION

Recurrent miscarriage is traditionally defined as three or more consecutive losses of pregnancy. This distressing problem affects approximately 1% of all women. By contrast, sporadic miscarriage affects 25% of all women who conceive a pregnancy. As such, sporadic pregnancy loss is the most common complication of pregnancy and it is important to recognize that the causes of sporadic and recurrent miscarriage are diverse.

Agreed that the spontaneous resolution rate of this condition is high, but the distress caused by repeated pregnancy failure and the ability of modern science to document an etiological factor in many cases justify the investigation of affected couples. Since women with recurrent pregnancy failure can experience miscarriages both early and late in pregnancy with a variety of clinical manifestations, there is unlikely to be a single etiology.

When to label as recurrent spontaneous abortion (RSA): after two or three pregnancy losses? Five percent of all couples trying to conceive have two consecutive miscarriages and 1% has three or more consecutive losses. Older the woman higher the risk for pregnancy loss. Outcome of the previous pregnancy is very vital in deciding when to start investigating. If there is a history of oligomenorrhea then it predicts a higher subsequent risk for miscarriage. However, a study carried out by us revealed that it is wise to start investigating a couple even after two losses if immunological cause is suspected.1

CHANCES OF CONTINUING THE PREGNANCY

When a subject presents with history of pregnancy losses this time early in pregnancy, her apprehension is rightfully expressed in knowing the chances of continuing this pregnancy. In a study carried out by us it was found that the maximum chances of missing this pregnancy again was in subjects in whom there were only recurrent pregnancy losses in the past.2 This is shown in Figure 1.

This data emphasizes the importance of research directed toward establishing the factor(s) that determine the outcome of a women’s previous pregnancy(s), which have a significant effect on the outcome of future pregnancies. However, in spite of our increasing knowledge about the details of implantation and early pregnancy, a clear etiology could not be identified in about 50% of the cases.3 This chapter reviews the work-up and management of factors that can lead to recurrent pregnancy loss.

GENETIC FACTORS AND RECURRENT MISCARRIAGES

Chromosomal abnormalities of the embryo are the most common cause of sporadic miscarriage, causing more than half of the early losses. A genetic etiology is less likely with late first-trimester or second-trimester losses. In women with a history of recurrent miscarriage, chromosomal
abnormalities of the embryo occur much less frequently. There is a tendency for successive abortuses to be karyotypically normal or karyotypically abnormal suggesting that some couples are at risk of recurrent aneuploidy. However, the risk of a subsequent miscarriage is higher when the index loss has a normal karyotype. The finding of an abnormal karyotype is invariably comforting to the affected couple who will readily be able to understand this cause of pregnancy failure.

Couples in which one or other partner carries a chromosome rearrangement are at risk of recurrent miscarriages with the loss of conceptuses with an abnormal karyotype. Chromosomal abnormalities are more common among men with an abnormal semen analysis. If three or more pregnancies are lost, it is important to evaluate with a karyotype from both partners.

The most common type of parental chromosomal abnormality is a balanced translocation (either reciprocal—65% or Robertsonian—35%) with a reported prevalence of 3–5% in couples with recurrent pregnancy failure, in contrast to a prevalence of 0.2% in an unselected population.

**Structural Chromosomal Anomalies and Recurrent Pregnancy Loss**

Structural chromosomal anomalies are higher in couples with history of RSA as well as past history of birth of anomalous or stillborn infants. When chromosomal anomalies are found in a conceptus aborted of RSA, over 50% are autosomal trisomies, 20% chromosomal monosomies, 19% polyplody, 3.8% structural anomalies and rest are mixoploidy. Most chromosomal abnormalities in RSA arise from errors in meiosis.

**Recurrent Aneuploidy and Recurrent Pregnancy Loss**

Chromosomal anomalies of the embryo are the most common cause of early pregnancy loss. Most chromosomal abnormalities result in disordered development, incompatible with prolonged intrauterine survival and livebirth. Couples in whom one or other partner carries a chromosomal rearrangement are at risk of recurrent pregnancy loss (RPL) with loss of conceptus with an abnormal karyotype.

An increased number of chromosome breaks and pericentric inversions are seen in recurrent abortion group. This presumably would lead to both, the loss of mitotically unstable elements during cell division and an increased rate of aneuploidy potentially contributing to early embryonic loss.

**Relevant Genetic Counseling**

Evidence is mixed as to whether chromosomal abnormalities tend to recur in subsequent pregnancies. Hassold studied 40 couples and found a 70% recurrence risk with a prior aneuploid pregnancy vs. 20% with a prior euploid pregnancy. Warburton et al. found no increased risk of chromosomal abnormalities in subsequent pregnancies after spontaneous abortions if the fetus carried an aneuploidy that is always lethal in utero or if the parents had normal chromosomes. Carriers of a translocation in chromosome 22 almost always miscarry; a woman with a translocation involving breaks in chromosome 13 or 14 has a 25% risk of spontaneous abortion. Empirically, the birth of a trisomic infant places a woman at an approximately 1% increased risk for a subsequent trisomic conceptus. There is a stronger tendency for ensuing abortion to be cytogenetically normal when index abortion has a normal karyotype. If atleast some of the antecedent abortions are trisomic, there probably is an increased risk for recurrence. Amniocentesis on chorionic villus (CV) biopsy should be encouraged in any pregnancy in couples with a previous abnormal karyotype because of the risk of an abnormal child. If aneuploidy is documented on a previous abortion, a centrally timed insemination is advocated based on animal studies relating aneuploidy to aging of ovum or sperm. The other choice is of donor insemination. If euploidy has been documented on a previous abortion, anatomic or endocrine factors should be corrected. Today, couples with serious high-risk abnormalities have the chance of pursuing a pregnancy by means of a donor sperm or in vitro fertilization (IVF) with donor oocytes (or both). The blastocysts are examined, and they are implanted only if they are chromosomally normal. Preimplantation genetic diagnosis (PGD) allows genetic screening of the embryos before transfer during an IVF cycle. A small opening is made on the zona pellucida of a cleavage stage embryo and one or two blastomeres are removed for genetic analysis.
Fluorescent in situ hybridization (FISH) is used to detect numeric and structural chromosomal anomalies, and polymerase chain reaction (PCR) is used to detect monogenic disorders. FISH analysis can be performed for 5–11 chromosomes. Several research groups have assessed whether PGD is beneficial for women with recurrent pregnancy loss. The results are controversial. PGD may not offer hope to all women with recurrent pregnancy loss, but there may be subgroups (e.g., based on age, number of previous losses, number of available embryos for testing) for whom its use is justified.

**ANATOMICAL CAUSES AND RECURRENT SPONTANEOUS ABORTION**

Congenital anomalies of the uterus have been cited repeatedly as an important cause of recurrent miscarriage, both in the midtrimester and in early pregnancy (Table 1). However, not all congenital defects cause pregnancy loss. For example, an arcuate uterus is usually associated with normal progression of a pregnancy, whereas a septate uterus is a frequent cause for loss. In order to cause early pregnancy loss, the embryo supposedly implants in an avascular part of the endometrium, such as a uterine septum, leading to arrested development and early pregnancy failure. For pregnancies to fail repeatedly implantation must be occurring in areas of abnormal vasculature in successive pregnancies.

The prevalence of uterine anomalies in women with recurrent miscarriage has been reported to be in the region of 10%. However, the prevalence in the general population is unknown and the majority of women with uterine anomalies probably have normal reproductive outcomes.

**Unicornuate Uterus**

Fetal pregnancies are lost in the second trimester. Uterus with a rudimentary horn is a doubtful risk factor for abortions. The possible mechanisms of abortions in cases of unicornuate uterus include decreased uterine capacity that does not permit adequate gestational growth and development, relative cervical incompetence contributing to midtrimester abortion and vascular anomalies in the distribution of uterine arteries in these cases.

**Uterus Didelphys**

Without a surgical correction, fetal survival rate in this condition is about 64%. Amongst all Müllerian anomalies, this condition has the best prognosis as regards the pregnancy outcome is concerned. Surgical procedures for treatment of pregnancy losses in this condition are rarely indicated. Benefits of metroplasty are not certain in this condition.

**Bicornuate Uterus**

Incomplete paramesonephric duct fusion produces bicornuate uterus. Women with bicornuate uterus can expect reasonable success (about 50%) in delivering a live child. Surgical correction by metroplasty is recommended in bicornuate uterus. It has been found that the incidence of cervical incompetence is increased with bicornuate uterus. It is therefore necessary to carry out a timely cervical cerclage in this condition.

**Septate Uterus**

The fibromuscular septum may be partial, complete or segmental. Diminished septal blood supplies, distortion of uterine cavity and associated cervical or hormonal abnormalities may be the causes of pregnancy loss. Also, pregnancy loss may be related to impaired embryo growth associated with septal implantation. Some reports put a 28–75% livebirth rate in cases of septate uterus. The surgical treatment recommended is hysteroscopic-guided septum transection.

UTERINE FIBROIDS

A common acquired anomaly of the uterus is fibroids. Submucous myomas deform the cavity, and the endometrium covering them is usually thin and inadequate for normal implantation. Fibroids in a submucous location can also be associated with pregnancy loss. The case is less clear with intramural and subserosal fibroids. In these locations, the size and the number of the fibroids will make a difference. Larger (> 4 cm) and multiple fibroids are usually associated with adverse pregnancy outcome, and their removal is recommended.16-17

CERVICAL INCOMPETENCE

Cervical incompetence is one acquired cause of RPL that is well-described. The phrase “cervical incompetence” was first used in the mid-19th century, and consideration of possible treatment began in the early part of this century, with surgical “repair” of the cervix being described in the 1930s and 1940s.18 However, it was the description of surgical cervical cerclage, and the subsequent successful outcomes, initially by Shirodkar in India,19 and then McDonald in Australia20 that provided the starting point for the present-day enthusiasm for cervical cerclage in cases of presumed cervical incompetence.

Incidence of cervical incompetence was put up to 0.5–1% of all pregnancies.21 It is known to cause second-trimester abortions. There are many causes that can produce cervical incompetence. These include congenital causes like diethylstilbestrol (DES) uterus and Müllerian anomalies. Acquired causes include a past history of D and C, D and E, conization, cautery and similar surgeries on the cervix.

Cervical incompetence as a cause of midtrimester miscarriage has been well-described. The diagnosis is usually made after a history of a painless midtrimester loss but our experience suggests that this condition is over diagnosed. Cervical cerclage is not associated with significant difference in the fetal survival rate between the cerclage and control groups. In addition, cerclage is associated with increased obstetrics intervention and an increased incidence of puerperal pyrexia.

Cervical incompetence is not a cause of early pregnancy loss and cervical cerclage is therefore not indicated in women with recurrent early pregnancy failure.

A diagnosis of cervical incompetence is usually made on the basis of the woman’s past obstetric history. Classically, this consists of one or more late second-trimester or early third-trimester losses, characterized by a rapid, often relatively pain-free delivery, commonly following the rupture of membranes prior to labor and in the absence of an obvious precipitating cause. This description of cervical incompetence is subjective (both on the part of woman and the obstetrician) and also retrospective.

Based on limited clinical information, elective cerclage for historical factors generally should be confined to patients with three or more otherwise unexplained second-trimester pregnancy losses or preterm deliveries. Cerclage should be performed at 13–16 weeks of gestation after ultrasound evaluation has demonstrated the presence of a live fetus with no apparent anomalies.

Shirodkar, in an effort to place the suture as near the internal os as possible, described opening the anterior fornix and dissecting away the adjacent bladder, before placing the suture submucosally, tied internally and the knot buried by suturing the anterior fornix mucosal opening. The McDonald technique requires no bladder dissection, and the cervix is closed using four or five bites with the needle to create a purse string around the cervix. The suture is then removed either electively or if labor ensues. Other methods of cervical suturing have been described (including the Wurm’s procedure, with two mattress sutures placed at right angles to each other), but present practice largely uses variants of McDonald or Shirodkar’s cerclage procedures.

One further development in the 1960s was the description of the transabdominal cerclage by Benson and Durfee in 1965,22 a technique now largely used after the failure of vaginal cerclage procedures or in the presence of congenital anomalies, particularly those produced by DES exposure. The original intention with the transabdominal approach was that the suture was inserted between pregnancies or in early pregnancy, and left in situ for the rest of the woman’s reproductive life, delivery being undertaken by cesarean section for each pregnancy.

The results of all these forms of treatment, however, are muddied by the same complication: The lack of a precise (and objective) diagnosis or definition of what constitutes cervical incompetence, a difficulty which is likely to blur the results of any study by not distinguishing effectively between cervical incompetence and other causes of recurrent second-trimester losses.

A cervical compliance score has been suggested whilst several years earlier a similar Cervical Resistance Index (CRI) was suggested by Anthony, Zlatnik and Burmeister23 who suggested the use of three scores to be measured at hysteroscopy: (1) the canal-cannula ratio (the upper cervical canal width compared to the hysteroscope width on an X-ray film taken during hysteroscopy); (2) the degree of difficulty of passing a No. 8 Hagar dilator and (3) the degree of traction required to pull a catheter out through the cervical canal with the balloon filled with 2 mL of saline (Table 2).

The measurement of cervical resistance, cervical compliance and cervical strength is logical in the face of a presumed diagnosis of cervical weakness. However, there is a significant disadvantage in the reliance on hysteroscopically based investigation, in that no investigation or diagnosis can be done during pregnancy due to the invasive nature of the testing. Transvaginal ultrasonography (USG) has been
used for diagnosis of cervical incompetence. Urgent, or therapeutic, cerclage often is recommended for women who have ultrasonographic changes consistent with a short cervix or evidence of funneling. Management of this group remains speculative because of the limited number of well-designed randomized trials. Evidence suggests that the use of a cervical stitch should not be offered to women at low or medium risk of midtrimester loss, regardless of cervical length by ultrasound. The role of cervical cerclage for women who have short cervix on ultrasound remains uncertain as the numbers of randomized women are too few to draw firm conclusions.\(^7\)\(^4\)

**INFECTIONS AND RECURRENT SPONTANEOUS ABORTION**

Many infections of the genital tract have been reported to be associated with sporadic pregnancy loss. Bacterial vaginosis, a polymicrobial anaerobic infection, has been implicated in the etiology of preterm labor,\(^25\)\(^26\) but its role in RPL is doubtful. *Treponema palladium* has been implicated in causing stillbirths and second-trimester abortions. The postulated mechanism of spontaneous abortions is fetal infection causing fetal death or severe malformations incompatible with fetal viability. However, *Treponema palladium* infection is not a cause leading to RSAs. 

Maternal infection with *Toxoplasma gondii*, cytomegalovirus, rubella and herpes (TORCH) can cause sporadic pregnancy loss but evidence that these organisms are associated with recurrent miscarriage is lacking. It is also very difficult to prove that microorganisms lead to repetitive pregnancy losses. In order to lend sufficient scientific support to this explanation, one would need to culture out the same micro-organism with each pregnancy loss and show that antimicrobial therapy effectively reduces the subsequent risk.\(^27\)\(^28\)

**ENDOCRINE DYSFUNCTION AND RECURRENT SPONTANEOUS ABORTION**

There is now good evidence that well-controlled diabetes is not associated with an increased risk of early pregnancy loss.\(^29\)\(^30\) Poorly controlled diabetic patients, however, do have an increased incidence of early pregnancy failure\(^31\) and so prepregnancy counseling of established diabetic patients is important with the aim of obtaining good preconceptual glycogenic control. There is no value in performing glucose tolerance tests in symptomatic women presenting with recurrent miscarriage, as these are invariably uninformative.

Similarly, thyroid dysfunction is often cited as an etiological factor for recurrent pregnancy loss\(^31\)\(^32\) but no direct evidence exists. Recent studies using radioimmunological techniques to measure thyroid function have shown no role of thyroid function tests in patients of RSA. It has been reported that the presence of thyroid autoantibodies is associated with an increased risk of miscarriage\(^33\)\(^34\) but it is likely that this finding is secondary to a generalized autoimmune abnormality rather than a specific endocrine dysfunction, since thyroid function tests are usually normal.\(^35\) Although thyroid function assessments are simple and cheap, their utility in RSA is so small that justification in asymptomatic women (for thyroid) with RSA is difficult. There is little justification, therefore, in screening symptomatic women presenting with recurrent pregnancy failure with thyroid function tests.

### Hypersecretion of Luteinizing Hormone

Miscarriage rate has been found to be significantly higher in patients with high luteinizing hormone (LH) levels than in those with normal LH levels. There is now good evidence that the presence of polycystic ovaries (PCOs) is associated with both subfertility and early pregnancy failure. In contrast to the normal population, who have a reported prevalence of PCO of 22%,\(^36\) the prevalence of PCO in women with a history of recurrent early pregnancy loss was found to be 82%\(^37\) and in infertile women attending for IVF the prevalence of PCO is as high as 50%.\(^38\)

The link between PCO and early pregnancy failure would appear to be hypersecretion of LH (Table 3). Studies have shown that women with elevated LH levels undergoing IVF\(^39\)\(^40\) or ovulation induction are less likely to conceive and have an increased incidence of early pregnancy loss compared to women with normal LH secretion. In a prospective study of 193 women conceiving spontaneously\(^41\)\(^42\) hypersecretion of

**Table 3:** Possible mechanism of action of the deleterious effect of hypersecretion of luteinizing hormone (LH) on the outcome of pregnancy

- Direct inhibition of oocyte maturation inhibitor (OMI) causing premature resumption of meiosis and the production of physiologically aged oocytes.
- Direct effect on endometrial function possibly via abnormal prostaglandin synthesis.
- Indirect effect on either the oocyte or endometrium via altered androgen production.
- Production of abnormal glycoforms of LH causing abnormal signal transudation.
LH was associated with a subsequent miscarriage rate of 65% compared to a rate of 12% in women with normal LH levels.

**Luteal Phase Defect and Recurrent Pregnancy Loss**

Luteal phase defect (LPD) has been characterized by inadequate, endometrial maturation resulting from insufficient progesterone production or shortened duration of the luteal phase. Progesterone plays an important role during implantation and pregnancy. Progesterone is required to induce secretory changes that prepare the endometrium for the arriving embryo. However, progesterone also has an immunomodulatory effect. It stimulates the production of progesterone-induced blocking factor that suppresses natural killer cell activity and increases the Th-2 response. This suppressive effect favors implantation and the progress of early development.

Luteal phase insufficiency used to be a common finding during the work-up of recurrent pregnancy loss. LPD is diagnosed on the basis of endometrial biopsies. When there is at least 2 days’ discrepancy between the histologic picture and the cycle day, LPD is diagnosed. Recently, however, it has been shown that many women with proven fertility have at least a 2-day discrepancy when evaluated. Another method for assessing the luteal phase is to measure progesterone levels (Day 21). Luteal phase progesterone is used to prove ovulation (value over 3 ng/mL), and values in excess of 10 ng/mL are considered adequate for the luteal phase. Other methods used to diagnose LPD include basal body temperature (BBT), USG of endometrium and others.

An association between the LPD and RPL is controversial. If a diagnosis of LPD is sought in a woman with recurrent pregnancy loss, it should be confirmed by endometrial biopsy. In addition to diagnosis, treatment of LPD is controversial.

**Ovarian Function**

Good quality oocytes are needed for a successful pregnancy. Pregnancy rates are lower and loss rates are higher with advanced reproductive age. Ovarian reserve testing serves the purpose of assessing the function of the ovaries. Among women 35 years and older, poor results for ovarian reserve testing have been shown to be associated with poorer quality oocytes. Also, women with elevated early cycle follicle-stimulating hormone (FSH) or elevated estradiol levels have been found to have higher rates of miscarriage.

**AUTOIMMUNE DISEASE AND RECURRENT SPONTANEOUS ABORTION**

Antiphospholipid antibody (APA) syndrome is an autoimmune condition that has profound bearing on obstetric conditions at times seemingly diverse. The association between raised circulating APAs and recurrent pregnancy failure is now well-established. The knowledge that some women with systemic lupus erythematosus have a poor reproductive outcome led to the discovery that the presence of circulating APAs is a marker for the poor outcome of pregnancy. Recurrent spontaneous missed abortions, intrauterine growth restriction (IUGR), recurrent stillbirths, accidental hemorrhage and thromboembolism are some diverse conditions that have this as its etiologic factor.

The primary APA syndrome, recurrent pregnancy loss, arterial and venous thrombosis or thrombocytopenia in the absence of overt autoimmune disease, are now well-documented.

Laboratory diagnosis of APA is currently done by enzyme-linked immunosorbent assay (ELISA) technique. Blood so collected is tested for APAs. Diagnosis is also helped by asking a history of allied complications of APA like RSA of missed type, recurrent stillbirths, recurrent IUGR, etc (Table 4).

Antiphospholipid antibodies or APA were identified to be of six types. Of these six, three are important for clinicians:

1. Anticardiolipin antibodies (ACAs)
2. Lupus anticoagulant (LAC)
3. Biologically false positive serological test for syphilis (BFPSTS).

Treatment

Nearly 18 different protocols have been tried over the period of years for the treatment of APA syndrome. But, the main stay is heparin and low dose aspirin. We use the following protocol:\(^\text{56}\)

- For low and moderate positive, aspirin in a dose of 1.2 mg/kg/day for 3 months—allow a conception—restart aspirin in the same dose from 12 weeks to 36 weeks.
- For high positive, aspirin in a dose of 1.2 mg/kg/day for 3 months. Allow conception—start aspirin from 12 weeks to 36 weeks (aspirin can be commenced as soon as the urine pregnancy test becomes positive).

As soon as pregnancy is diagnosed and fetal heart activity is seen on USG, we give 5,000 IU of heparin twice daily subcutaneously till 36 weeks of pregnancy. This combination of aspirin and heparin gives the best results.

Evidence indicates that combined unfractionated heparin and aspirin may reduce pregnancy loss by 54%. Large, randomized controlled trials with adequate allocation concealment are needed to explore potential differences between unfractionated heparin and low molecular weight heparin.\(^\text{57}\)

Currently, there is no reliable evidence to show that steroids improve the livebirth rate of women with recurrent miscarriage associated with APA when compared with other treatment modalities; their use may provoke significant maternal and fetal morbidity. In our study of more than 300 cases now subjects testing positive for APA were given the above treatment protocols. In the group where treatment could be given preconception as well as postconception, full-term delivery rates achieved were 88.3%. In the group where only postconception treatment could be given, the same rate was 72.3%. The incidence of pre eclampsia (PE) remote from term declined from 26.7% to 3.3%.\(^\text{56}\)

ALLOIMMUNE CAUSES AND RECURRENT SPONTANEOUS ABORTION

It has been suggested that a necessary prerequisite for successful pregnancy involves maternal recognition of the embryo, leading to a protective immune response. Further a failure to mount the appropriate maternal immune response will lead to recurrent pregnancy loss. Because immunological aberrations might be the cause of miscarriage in some women, several immunotherapies have been used to treat women with otherwise unexplained recurrent pregnancy loss. An increased degree of human leukocyte antigen (HLA) sharing between the parents could be responsible for the lack of maternal immune recognition is now strongly disputed.\(^\text{58,59}\)

Evidence suggests that immunotherapy including paternal cell immunization, third party donor leukocytes, trophoblast membranes and intravenous immune globulin provide no significant beneficial effect over placebo in improving the livebirth rate.\(^\text{60}\)

The use of immunotherapy should no longer be offered to women with unexplained recurrent miscarriage and routine tests for HLA type and antipaternal cytotoxic antibody should be abandoned.

UNEXPLAINED RECURRENT PREGNANCY LOSS

In about 50% of couples with recurrent pregnancy loss, an evaluation including parental karyotypes, hysterosalpingography or hysteroscopy and APA testing will be negative. Informative and sympathetic counseling appears to serve an important role in this situation. Livebirth rates between 35% and 85% are commonly reported in couples with unexplained RPL who undertake an untreated or placebo-treated subsequent pregnancy.\(^\text{61,62}\) Meta-analysis of randomized, prospective studies suggests that 60–70% of women with unexplained RPL will have a successful next pregnancy.\(^\text{63}\) Data suggest that the use of empirical treatment in women with unexplained recurrent miscarriage is unnecessary and should be resisted.

PSYCHOLOGICAL ASPECTS OF RECURRENT SPONTANEOUS ABORTION

Tender loving care: It consists of psychological support and weekly medical and USG examinations. Follow-up visits are advised after 2 weeks to share medical information and counseling about normal responses in the form of sadness, guilt and anger, depression, lack of concentration and difficulty at work. In case of considerable depression beyond 4–6 months, it is advisable to refer to an informed professional counselor and others with similar losses.

ENDOMETRIOSIS AND RECURRENT SPONTANEOUS ABORTION

A possible association between endometriosis and spontaneous abortion has been suggested in mostly uncontrolled and/or retrospective studies. Some controlled studies evaluating the association between endometriosis and spontaneous abortion showed important methodological shortcomings: Heterogeneity between cases and controls, analysis of the abortion rate before the diagnosis of endometriosis, and selection bias of study and control groups. On the basis of controlled prospective studies, there is no evidence that endometriosis is associated with (recurrent) pregnancy loss or that medical or surgical treatment of endometriosis reduces the spontaneous abortion rate.\(^\text{64}\) In programs of assisted reproduction, some studies have shown that the number and quality of oocytes, the fertilization rate, and the implantation rate per embryo may be reduced in women with endometriosis, but this observation has not been confirmed by other investigators.
TOXIC/ENVIRONMENTAL EFFECTS

Although a common concern of patients, environmental factors rarely have been linked to sporadic pregnancy loss, and no associations between environmental factors and RPL have been established. Likewise, occupational exposures to certain products, such as certain organic solvents, rarely have been linked to sporadic pregnancy loss. However, no associations between occupational exposure or working itself and RPL have been established. Study results are conflicting on the association of smoking, use of alcohol, and use of caffeine with sporadic pregnancy loss. They may act in a dose-dependent fashion or synergistically to increase the rate of sporadic pregnancy loss. However, none of these habits has been associated with recurrent pregnancy loss. Exercise does not appear to increase the rate of sporadic pregnancy loss, particularly in women in good physical condition, and there are no studies showing the effect of exercise in women with recurrent pregnancy loss.

Diagnosis

The diagnostic work-up has to be complete, as several factors could simultaneously be responsible for the recurrent reproductive failure. First, it is important to review the past obstetric history. Details about previous pregnancy losses may yield important clues. All prior pregnancies should be examined in detail, with attention to gestational age at time of loss, complications, USG findings, pathology reports, and chromosomal analyses. The etiology may differ if the loss occurred in the first vs the second trimester. The physical examination could also reveal important details. The body weight and height need to be measured, signs of hyperandrogenism should be looked for, and the breasts should be checked for the presence of galactorrhea. The pelvic examination may identify congenital and acquired genital tract lesions (e.g. vaginal septum, duplicated cervix, uterine enlargement, adnexal masses). Besides a complete history and a thorough physical examination, imaging studies and laboratory testing complete the evaluation.

Imaging Studies

Imaging studies play an important role in diagnosing uterine anomalies. A transvaginal ultrasound is usually the initial step. The size and position of the uterus can be evaluated, fibroids can be detected, and some other anomalies might be suggested by the ultrasound findings (e.g. duplicated cervix, uterus, uterine septum, unicorneuate uterus). A careful examination of the endometrial echo may lead to the detection of polyps and scarring. Saline infusion into the cavity improves the diagnostic accuracy of the ultrasound examination.

The routine use of HSG as a screening test for uterine anomalies is questionable. It is associated with patient discomfort, a risk of pelvic infection and radiation exposure and it is no more sensitive than the noninvasive pelvic ultrasound with (or without) sonohysterography.

Hysteroscopy offers a more precise evaluation of the cavity. During the procedure the intracavitary structures can be directly visualized and directed biopsies can be obtained when indicated. The intramyometrial extension of fibroids cannot be assessed, however, and therefore the size estimate remains imprecise. Hysteroscopy alone cannot differentiate between a septate uterus and a bicornuate uterus; laparoscopy is required to complete the evaluation.

Nowadays, hysteroscopy is the primary surgical method for the correction of the various intrauterine pathologies. Laparoscopy is also used for guidance during hysteroscopy, and for the removal of subserosal/intramural fibroids. Magnetic resonance imaging (MRI) is an accurate noninvasive technique for the evaluation of uterine anomalies. Its limited availability and the cost of the test, however, are drawbacks. Intravenous pyelogram is recommended during the work-up of congenital anomalies. Defects in the urinary tract are commonly seen when a uterine anomaly is diagnosed.

Laboratory Evaluation

Laboratory evaluation plays a very important role in the work-up of recurrent pregnancy loss.

- A karyotype should be obtained from both partners.
- Men with severe oligozoospermia (< 5 million/mL) should also be evaluated for Y-chromosome microdeletions.
- Antiphospholipid antibodies need to be measured on two separate occasions at least 6 weeks apart.
- Microbiological studies of vaginal secretions are unlikely to reveal any pathogens that are responsible for recurrent loss.
- Patients with recurrent vaginal infections, on the other hand, should be evaluated and treated as necessary.

TREATMENT

Surgical Treatment

Some of the anatomic defects require surgical correction, but others do not. Therefore, it is very important to know the exact anomaly. Endoscopic procedures are most commonly used to correct the defect. Intrauterine pathologies (e.g. septum, submucous fibroids, polyps) can be removed during hysteroscopy. A septum is most commonly excised with scissors, but laser or resection can also be used. Better hemostasis is achieved (bleeding is typically minimal) with the latter procedures, but thermal injury might lead to scar formation. Intramural and subserosal fibroids are removed via the laparoscopic approach. It is important to mention that uterine rupture during pregnancy has been reported following the laparoscopic procedure. Uterine artery embolization is
another intervention that has been used in the management of symptomatic myomas but it has a limited utility in these cases due to a possible risk of ovarian failure. Laparotomy has a very limited role in the management of congenital anomalies among women with recurrent abortion. As a bicornuate uterus is usually associated with problems during the third trimester of the pregnancy, the procedure should be limited to very few well-selected cases with recurrent second-trimester and third-trimester problems. When surgery is performed, the unification of the 2 horns with a bicornuate uterus is carried out via laparotomy (Strassman procedure). The procedure often leaves a small cavity with scarring, making implantation difficult.

**Medical Treatment**

Patients with pregestational diabetes should receive adequate insulin replacement. Ideally, the hemoglobin A\(_1c\) (HbA\(_1c\)) should be less than 7.5%. Thyroid dysfunction should also be treated to achieve euthyroidism before pregnancy. Most cases of hyperprolactinemia are managed medically. There are various treatment options to manage an inadequate luteal phase. Stimulation of follicle growth will typically result in a better quality secretory phase. The simultaneous growth of several follicles will result in the formation of many corpora lutea and, therefore, larger progesterone output. Ovulation induction also has an impact on endometrial development. Another option is to supplement progesterone to support the luteal phase. Typically, vaginal or intramuscular preparations are used and started in the luteal phase; when pregnancy follows, progesterone is continued up to 8–10 weeks of gestation.

There is no evidence to support the routine use of progesterone to prevent miscarriage in early to midpregnancy. However, further trials in women with a history of recurrent miscarriage may be warranted, given the trend for improved livebirth rates in these women and the finding of no statistically significant difference between treatment and control groups in rates of adverse effects suffered by either mother or baby in the available evidence. Insulin-sensitizing agents, most commonly metformin, have been widely used for the management of women with polycystic ovary syndrome (PCOS). Metformin is effective for ovulation induction. When continued during pregnancy, it has been associated with a lower rate of spontaneous abortion. Metformin is a category B drug. Its use during the first trimester should be considered in subjects with PCOS who have a history of adverse pregnancy outcome.

Recent Trends in the Management of Recurrent Pregnancy Loss

Intrauterine Growth Restriction: Diagnosis and Management

INTRODUCTION

Intrauterine growth restriction (IUGR) remains a major obstetric and neonatal challenge. It is a condition which may take a while, before being diagnosed. Once diagnosed, it is difficult to treat with no specific cure or therapy available.

Perinatal asphyxia involving multiple organ systems is one of the most significant problems in growth-restricted low-birthweight infants. These cases have an increased risk of stillbirth, preterm labor, neonatal morbidity and mortality due to birth asphyxia, meconium aspiration, neonatal sepsis, hypoglycemia and hypothermia.

Long-term follow-up studies have demonstrated that babies who suffered intrauterine growth retardation are more likely to develop hypertension, coronary artery disease, and diabetes in adult life.

Thus, by identifying this condition early and instituting appropriate management—perinatal morbidity and mortality can be reduced and possibly long-term health problems in the individual avoided.

In India, according to the recent United Nations International Children’s Emergency Fund (UNICEF) survey, the incidence of IUGR is 25–30%.

DEFINITION OF INTRAUTERINE GROWTH RESTRICTION

Intrauterine growth restriction refers to a condition in which a fetus is unable to achieve its genetically determined potential size. This functional definition seeks to identify a population of fetuses at risk for modifiable but otherwise poor outcomes.

The most widely used definition of IUGR is a fetus whose estimated weight is below the 10th percentile for its gestational age and whose abdominal circumference (AC) is below the 2.5th percentile. At term, the cut-off birth weight for IUGR is 2,500 g (5 lb, 8 oz). This term is often erroneously used as synonymous of small for gestational age (SGA). Fetal growth is dependent on genetic, placental and maternal factors. The fetus is thought to have an inherent growth potential that, under normal circumstances, yields a healthy newborn of appropriate size. The terms “IUGR” and “SGA” are often used interchangeably. The IUGR fetus is a fetus that does not reach its potential of growth; whereas the SGA fetus does reach its potential of growth (Table 1).

In other words, a fetus who has a potential of growth at the 50th percentile but because of maternal, fetal, or placental disorders occurring alone or in combination, becomes growth restricted (birth weight < 10th percentile) is an IUGR fetus and he is at risk for adverse perinatal outcome. A fetus with a potential of growth at the 7th percentile who reaches Table 1: Comparison between intrauterine growth restriction (IUGR) and small for gestational age (SGA) fetuses

its potential of growth (7th percentile) is not an IUGR fetus but a SGA fetus. He is a normal small fetus and he is not at risk for adverse perinatal outcome.

The two components that are necessary to define an IUGR fetus are:
1. Birth weight < 10th percentile
2. Pathologic process that inhibits expression of the normal intrinsic growth potential.

The two components that are necessary to define a SGA fetus are:
1. Birth weight < 10th percentile
2. Absence of pathologic process.

**ANTEPARTUM RECOGNITION**

**Medical and Obstetric History**

A detailed medical history is mandatory to identify patients at high risk for IUGR. Mothers with significant medical or obstetric problems such as chronic hypertension, toxemia of pregnancy, chronic renal disease, twin gestation, diabetes are at high risk for IUGR fetuses. A patient with prior delivery of an IUGR baby is at high risk of having a similar problem in the present pregnancy.

**Uterine Fundal Height**

*Clinical evaluation of fetal and uterine size.* Clinical assessment of fetal growth includes estimating fetal size by traditional obstetrical manual examination and by measuring the uterine fundal height.3 It is an essential, inexpensive component of prenatal care and a simple screening tool for identifying mothers who would benefit from further, more definitive sonographic investigation.

Use the tape measure with the centimeters on the underside to reduce bias. Secure the tape measure at the fundus with one hand. Measure from the top of the fundus to the top of the symphysis pubis. The tape measure should stay in contact with the skin. Measure from the top of the fundus to the top of the symphysis pubis. The tape measure should stay in contact with the skin. Measure along longitudinal axis of uterus, note metric measurement. Record the metric measurement and plot it on the growth chart (Fig. 1).

![Customized antenatal growth chart](image-url)
Normal variability in measurement means that the slope will alter from one measurement to another. The line may cross centiles, but the overall slope of the curve should not be static (no growth over 2–3 weeks) and become abnormal if the slope falls away in subsequent measurements. In the case of normal fundal height growth, the measurements should reflect the curve on the customized charts. Using these charts in very small and very large women should reduce the number who would be referred for ultrasound assessment.

**Confirm Clinical Suspicion with Sonography**

Ultrasound biometry of the fetus is now the gold standard for assessing fetal growth, especially AC; estimated fetal weight derived from biparietal diameter (BPD) or head circumference (HC), AC and femur length (FL); and longitudinal progression of fetal growth.

Sonography is also capable of classifying the growth restriction on the basis of the presence or absence of symmetry among different anatomical structures.

*Type I IUGR*: The fetuses that are symmetrically small and have normal head-to-abdomen and femur-to-abdomen ratios.

*Type II IUGR*: The fetuses that have an AC smaller than the HC.

*Type III IUGR or intermediate IUGR*: The fetuses that are symmetric initially but become asymmetric later in pregnancy.

The most sensitive indicator of symmetric and asymmetric IUGR is the AC, which has a sensitivity of over 95% if the measurement is below the 2.5th percentile. Accurate dating of the pregnancy is essential in the use of any parameter. In the absence of reliable dating, serial scans at 2- or 3-weeks intervals must be performed to identify IUGR. It should always be remembered that each parameter measured, has an error potential of about one week up to 20 gestational weeks, about 2 weeks from 20 weeks to 36 weeks of gestation, and about 3 weeks thereafter.

Also useful is the ratio of the HC to the AC (HC/AC) (Figs 2A and B). Between 20 weeks and 36 weeks of gestation, the HC/AC ratio normally drops almost linearly from 1.2 to 1.0. The ratio is normal in the fetus with symmetric growth restriction and elevated in the infant with asymmetric growth restriction.

The difference between symmetric and asymmetric IUGR fetuses is shown in Table 2.

Another important use of ultrasound is estimating the amount of amniotic fluid. A decreased volume of amniotic fluid is closely associated with IUGR. Significant morbidity has been found to exist in pregnancies with an “amniotic fluid index (AFI)” value of less than 5 cm.

**Femur-to-Abdomen Ratio**

This compares the FL (Fig. 3) that is minimally affected by fetal growth impairment with the AC, which is most affected.

**Figs 2A and B:** Measurement of fetal circumferences. (A) Head circumference, (B) Abdominal circumference
Fetus as a Patient

Femur to abdomen (F/A) ratio remains constant after 20 weeks. A high F/A ratio indicates IUGR. When the F/A ratio is normal, the fetus may be small and healthy or may have symmetric IUGR.

**Fetal Ponderal Index**

Another ultrasound measurement useful for the diagnosis of fetal malnutrition is the fetal ponderal index (PI). The fetal PI is obtained by dividing the estimated fetal weight by the third power of the FL.

**ETIOLOGY (TABLE 3)**

Once diagnosed, one needs to find the cause of IUGR.

**INVESTIGATION**

A careful search for the causes of IUGR should be made, especially when IUGR presents early in pregnancy. Factors such as smoking, alcoholism, drug addiction, or proteinuric hypertension should be fully investigated.

Screening for evidence of recent maternal infection with toxoplasmosis, protozoa, rubella, chickenpox, and herpes viruses can be considered if fetuses are symmetrically small.

On ultrasonography (USG) anomalies should be ruled out, aneuploidy markers looked for carefully.

Karyotyping is usually not indicated in the isolated mild form of IUGR because the risk of aneuploidy remains remote. On the other hand, karyotyping should be considered when IUGR is severe but the Doppler scan is normal, or when IUGR is associated with the development of fetal anomalies.

In late second trimester the causes could be preeclampsia, diabetes or other medical disorders in the mother.

**Classification on the Basis of the Etiology**

**Intrinsic IUGR:** These fetuses are small because of fetal conditions as intrauterine infections or chromosomal abnormalities.

**Extrinsic IUGR:** These fetuses are affected due to an element outside of the fetus, like a placental condition or a maternal disease.

**Combined IUGR:** These fetuses are affected due to a combination of both the intrinsic and extrinsic factors.

**Idiopathic IUGR:** The cause of fetal growth failure is unknown.

**MANAGEMENT**

**Maternal Management**

**Bed Rest**

Bed rest has been the mainstay of IUGR therapy as it reduces the catecholamine release, improves central intravascular volume and improves uterine perfusion, resulting in better fetal nutrition. In practice “restricted bed rest” is what is
advised, i.e. an hour’s rest after breakfast, 2 hours after lunch and an 8 hour’s rest at night. Patients find it easier to comply with.

**Diet**

High protein diet has been advised with some improvement, provided it is started early in pregnancy. Evidence suggests that it does help the undernourished but may not be very useful for the well-nourished patients. However, we must remember that in our clinical setting, where a lot of ignorance and false beliefs are prevalent, the pregnant woman may not be eating right! Thus, the role of diet is important.

**Supplements**

Folic acid and zinc supplementation has been shown to be associated with some benefit in IUGR prone patients. Fish oil contains high levels of eicosapentaenoic acid which reduce synthesis of thromboxane and increase the prostacyclin levels, thus promoting vasodilatation. Hence, it is recommended as a therapeutic option by some workers. Some studies also suggest magnesium as a mode of treatment.

**Parental Nutrition**

Studies using parenteral solutions of 10% dextrose/fructose and 17% amino acids have shown an increase in the birth weight with some reduction in perinatal mortality in undernourished, but there is no evidence to suggest they would help the well-nourished patient.

**L-arginine**

This amino acid improves growth hormone-releasing hormone (GH-RH) secretion, with consequent increase of plasmatic GH influencing somatic growth. L-arginine moreover, is the obligatory precursor for nitric oxide (NO) enzymatic synthesis (endothelial-derived relaxing factor). Nitric oxide helps the prolapse of smooth musculature and, consequently, the improvement of placental blood circulation. Studies have shown that the total antioxidative activity in blood serum decreased in pregnancy connected with IUGR. L-arginine treatment decreased the oxidative stress risk. Carbonyl groups are the elements connecting protein structure; high concentration of carbonyl groups means high risk of protein destruction. L-arginine prevented protein damage in IUGR by decreasing the carbonyl groups in the process of treatment.

But, even though experimental studies have shown a positive aspect of treatment with L-arginine—no large study has yet conclusively confirmed it.

**Aspirin**

Low-dose aspirin therapy has been tried as antiplatelet agent, as it shifts the balance of thromboxane-prostacyclin in favor of the latter, but reports of its efficacy are quite contradictory. Wallenburg et al. studied a population of women at high risk for IUGR in a nonrandomized trial using historic controls. They noted a decline in the rate of IUGR from 61.5% in the historic controls to 13.3% in those treated with aspirin. But, the collaborative low-dose aspirin study in pregnancy (CLASP) trial failed to show any benefit in low risk mothers, but several other studies showed improvement in birth weights in the treated groups as compared to the controls, in high-risk population. To be effective, aspirin therapy should be started in first trimester itself. Intrauterine growth restriction treatment by low-dose aspirin had beneficial but nonsignificant impact on umbilical and middle cerebral artery (MCA) blood flow.

**Heparin**

The use of heparin is justified if antiphospholipid antibody (APLA) syndrome is proved.

**Amnioinfusion**

Reports of amnioinfusion helping are in general related to use in labor to decrease the incidence of meconium aspiration, or in a case of severe oligohydramnios—to do a targeted scan it may be helpful.

**Counseling the Patient**

The patient must understand the importance of her cooperation and involvement in the treatment for a good outcome.

**Monitoring the Fetus**

These patients need a surveillance plan that maximizes gestational age while minimizing the risks of neonatal morbidity and mortality.

**Fetal Biometry**

Serial measurements of “fetal biometry”—following the fetal growth by serial measurements—every 3 weeks give a fair idea of interval growth.

**Fetal Kick Count**

Patient is asked to maintain a kick count chart—and if there are less than 10 movements in 12 hours to report—when further testing would be necessary.
Amniotic Fluid Index

Measuring the amniotic fluid reflects the fetal health and a good amount of fluid can be reassuring. A fall below AFI 5 cm is considered dangerous and Doppler studies or nonstress test (NST) are indicated.

Nonstress Test

A satisfactory NST is reassuring—but a nonreactive pattern demands further evaluation of fetal status by Doppler studies.

Biophysical Profile

It is excellent for the identification of the nonhypoxic SGA fetus but can be a time-consuming exercise in diagnosing hypoxic IUGR and thus is not a very favored investigation. Cordocentesis is not recommended, as it has a procedure-related fetal mortality of about 1% and it represents merely a snap-shot of the fetal acid-base and biochemical states.

Doppler Studies

Currently, the two vessels yielding the best information in the fetus with IUGR appear to be the umbilical artery and MCA.

Use umbilical artery Doppler as the primary surveillance tool.

A systematic review with meta-analysis has provided compelling evidence that the use of umbilical artery Doppler to monitor high-risk fetuses reduces perinatal morbidity and mortality. In addition, there was a significant reduction in the number of antenatal admissions and inductions of labor associated with Doppler use. A study comparing fetal heart rate monitoring, biophysical profile and umbilical artery Doppler found that only umbilical artery Doppler had value in predicting poor perinatal outcomes in SGA fetuses. Use of Doppler does not lead to increased interventions as the rates of positive tests are low (2.7% of all umbilical artery tests in high-risk women). There is evidence that use of Doppler ultrasound to manage SGA fetuses reduces the use of resources compared with cardiotocography.

Ductus venosus Doppler: Severe Doppler changes in the ductus venosus occur late in the natural history of fetal growth restriction. There is strong empirical support for expeditious delivery of cases with significant changes in ductus waveforms. On this basis, it also seems that a good case could even be made for delivering fetuses before development of ductus venosus abnormalities.

How Often and When?

The frequency of fetal monitoring depends on the findings of various tests. Small for gestational age (SGA) fetuses with an otherwise normal fetal assessment can be monitored fortnightly, while those with abnormal Doppler results and/or oligohydramnios require more frequent monitoring, or delivery. If an elevation of the pulsatility index of the umbilical artery or oligohydramnios is found, twice-weekly cardiotocography, weekly Doppler studies, and measurement of the AFI are warranted. In pregnancies that are complicated by absent or reversed end-diastolic umbilical artery flow, daily fetal monitoring is needed if delivery is not considered.

Treatment of IUGR is largely limited to early delivery. The timing of delivery depends on the results of fetal monitoring tests and the gestational age (Flow chart 1).

Delivery is indicated when there are abnormal readings from cardiotocography or a low score on the biophysical profile. Doppler studies have shown that absent or reversed end-diastolic velocity waveforms in the umbilical artery are associated with high perinatal mortality and morbidity. Fetal hypoxia and acidosis have been found to be associated with pregnancies that are complicated by the loss of end-diastolic flow. Absent or reversed end diastolic umbilical artery flow merits delivery if the neonate of that gestational age or with that estimated birth weight can be handled by the local neonatal service.

There is also a current trend towards earlier delivery. Recent studies report that growth-retarded fetuses who are acidic during intrauterine life or exhibit antepartum abnormal heart rate tracings show poor neurological development at 2 years.

Growth-retarded fetuses with abnormal fetal Doppler studies of the descending thoracic aorta have a much higher neonatal mortality rate from necrotising enterocolitis and fetal hemorrhage.

While delivery of the term growth-retarded fetus is indicated when there are abnormal Doppler measurements, it is still controversial whether a preterm pregnancy should allow fetal maturity to be reached; the fetus may then become acidotic. Alternatively, the fetus could be delivered earlier to avoid damage from hypoxia and/or acidosis. It is not known whether the benefits of delivery at the stage of fetal hypoxia, but without acidosis, outweigh the risks of prematurity.

This issue will be addressed in the growth restriction intervention trial. The current recommendation is that results of fetal monitoring tests other than Doppler studies should also be taken into account. Both mother and obstetrician may find it difficult to face the situation of intrauterine death. In contrast, delivery by cesarean section may lead to early neonatal mortality or severe handicap, and could cloud the future obstetrical performance of the mother. Proper counseling is essential.

Harman and Baschat’s integrated fetal testing for IUGR, in increasing order of severity from one (least severe) to five (most severe), is described in Table 4.
Points to be Considered in Timing Delivery

- Administer steroids, if gestation is below 36 weeks.
- Deliver in a unit where optimal neonatal expertise and facilities are available.
- When end diastolic flow is present (PED), delay delivery until at least 37 weeks, provided other surveillance findings are normal.
- When end diastolic flow is absent or reversed, admission, close surveillance and administration of steroids are required. If other surveillance results (biophysical profile, venous Doppler) are abnormal, delivery is indicated.

CONCLUSION

Intrauterine growth restriction can occur in otherwise uncomplicated pregnancies. Because of the ill effects on the fetus its antenatal diagnosis and management is important. Because no effective treatments are known, the aim of every obstetrician is to deliver the most mature fetus in the best physiological condition possible while minimizing the risk to the mother.

22. Divakar H. The obstetrician and the low birth weight baby.
INTRODUCTION
The number and rate of twin pregnancies has increased dramatically in the last two decades. Twin pregnancies are associated with an increased risk of perinatal morbidity and mortality. The bulk of these arise from preterm deliveries and low birth weights. They also face problems which are unique to twin pregnancies such as monoamnionicity, discordant growth, twin-to-twin transfusion syndrome (TTTS) and death of one twin. This chapter does not aim to cover all the aspects of care of twin pregnancies in pregnancy and labor. We have covered areas which are most relevant in improving perinatal outcome and do not have clear guidelines on care.

VANISHING TWIN
The incidence of twin pregnancies is greater in the first trimester than the incidence of twins at birth. A very wide range (21-70%) of incidence is quoted in the literature of the “vanishing twin” phenomenon. This phenomenon is often associated with bleeding, but the prognosis of the remaining fetus is good. The risk of spontaneous loss of the pregnancy with a vanishing twin is similar to the risk in other pregnancies that are complicated with first-trimester bleeding. However, pregnancies complicated with a vanishing twin are associated with an elevation of the maternal serum alpha-fetoprotein level and amniotic fluid alpha fetoprotein. This may lead to false results with the triple marker test.

PREVENTING PRETERM DELIVERY
A majority of twins are delivered before maturity. About half are delivered by 34 weeks and 90% by 37 weeks gestation. Preterm births are the leading cause of perinatal morbidity and mortality in twin pregnancies. Spontaneous labor or preterm prelabor rupture of membranes account for 54 and 22% of preterm twin births. These may be looked upon as avoidable or at least predictable. Current efforts are directed toward optimizing and predicting the time of delivery. Various efforts have been in the form of cervical assessment, cerclage, progesterone, hospitalization and bed rest, home uterine activity monitoring (HUAM), antibiotics, tocolysis and steroid use.

Routine Hospitalization for Bed Rest
Routine hospitalization with bed rest is not helpful in prolonging twin pregnancies. A study of 141 twin pregnancies randomized to outpatient care with normal activities or to hospitalization with restricted activities showed no differences in mean birth weight or mean gestational age at delivery between the two groups. Another study showed only a small increase in the birth weight with hospitalization but no appreciable improvement in the gestational age at delivery. Neonatal morbidity or mortality were not reduced in either study.

Cervical Assessment
Ultrasound assessment of the cervix is more accurate than digital examination. A 25-mm cut-off at 23 weeks gestation
has been used as a negative predictor for preterm and very preterm births. The false negative rate ranged from 1.2% at 28 weeks to 18.6% at 35 weeks. There are no studies evaluating the cervical length earlier in pregnancy. The clinical usefulness of ultrasound cervical assessment as a routine evaluation is questionable because of the lack of proven treatments affecting outcome.

**Cervical Encirclage**

There are no studies to assess the role of prophylactic cerclage in twin pregnancies. In twin pregnancies identified to have a short cervix (<25 mm) in the mid trimester, there was no significant prolongation of the gestational period with a cerclage. In fact, a meta-analysis of twins with short cervical length undergoing cerclage showed an increase in the rate of preterm delivery. These studies, however, pertain to patients who have undergone cervical assessment after 20 weeks of pregnancy. It would be interesting to know the impact of cerclage at earlier gestations.

**Tocolysis**

A double-blind, controlled study of the prophylactic use of oral salbutamol in 144 women with twins (74 on salbutamol and 70 placebo) showed no difference in the length of gestation, birth weight, or fetal outcome between the study and control groups. Complications occur more often with the use of tocolytic therapy in multiple gestations than in singletons. This is the result of a greater increase in plasma volume and cardiac output that occurs in twins compared with single gestations. Beta mimetic use gives similar delay in delivery of twins as compared to singletons.

**Steroids**

Meta-analysis does not show a reduction in the incidence of respiratory distress syndrome. It is likely that this may be due to small study group numbers. However, the use of corticosteroids to enhance fetal lung maturation in multiple gestations in preterm labor and impending delivery (<34 weeks gestation) is recommended by most professional bodies in their guidelines. There is no evidence to support the use of prophylactic corticosteroids. A study examined the use of prophylactic steroids every 2 weeks between 24 weeks and 32 weeks. There was no benefit in reducing respiratory distress syndrome. Term neonates in the study group weighed 129 g less as compared to the ones treated with placebo.

**ANTENATAL CARE**

Twins are a high-risk pregnancy. As per routine, such pregnancies are subjected to more frequent antenatal visits. Though it is not clear whether such an approach improves outcome, it could possibly lead to earlier recognition of the onset of hypertension.

**Genetic Testing**

With increasing maternal age, the incidence of both twin gestations and fetal aneuploidy increases. In monozygotic twin gestations, in which both fetuses have the same karyotype, the risk of fetal aneuploidy is the same as the age-related risk for a singleton. However, in dizygotic twin pregnancies, the risk of fetal aneuploidy is twice the maternal age risk for a singleton pregnancy. Scant information is available concerning maternal serum screening for aneuploidy in twin gestations. Currently, the reliability of the serum screening for Down syndrome in twins is unknown. In terms of invasive tests, chorion villus sampling and midtrimester amniocentesis under ultrasound guidance are as safe and effective for prenatal diagnosis as compared to singleton pregnancies. Careful ultrasound examination to map and label fetal positions relative to the maternal orientation, fetal membranes, and placental localizations is of paramount importance to sample the twins correctly. The use of dyes to identify the fetuses is avoidable.

**Antepartum Surveillance and Fetal Well-Being Tests**

Fetal growth in twin pregnancies after 30 weeks of gestation lags behind the growth of singleton pregnancies. Also, there can be unequal or intrapair discordant growth. Therefore, serial ultrasounds at 2-4 week intervals are done to monitor the interval growth of twin gestations in the third trimester. The estimated fetal weight provides the best discriminator for discordant growth. The estimation of “amniotic fluid volume” is problematic. Amongst the fetal well-being tests, nonstress test and Doppler velocimetry are more predictive of fetal well-being than amniotic fluid volume and biophysical profile. As in singleton pregnancies, “Doppler ultrasound” assessing the umbilical artery systolic/diastolic ratios is useful in diagnosing growth restriction. The positive predictive value of an abnormal Doppler outcome was 90%, and the negative predictive value was 95.6% in twin pregnancies.

**When is Term?**

The growth of twins begins to decline after 38 weeks of gestation. After 38 weeks gestation, the perinatal death rate and intrauterine growth restriction of twin pregnancies increase substantially. The data would therefore suggest that twins are “post-term” after 38 weeks. The ideal time of delivery for an uncomplicated twin pregnancy is still uncertain. However, the literature appears to support delivery by 38 weeks of gestation.
**Monoamniotic Twinning**

About 1% of all twin pairs are monoamniotic. The risk specific to this situation is cord entanglement. It appears that this event generally occurs before 32 weeks of pregnancy. This suggests that prophylactic preterm birth may not be indicated. The optimal route of delivery is not determined, but in general, cesarean section is recommended.

**Death of One Twin**

Death of one twin occurs in about 5% of all twin pregnancies. It is the second twin that is more likely to lose. In addition, the surviving twin is five times more likely to succumb in monochorionic pregnancies as compared to dichorionic twins. This likelihood is strongly related to birth weight discordance. Survivors of monochorionic twin pregnancies are more likely to suffer from anemia and intracranial pathology as compared to dichorionic twin survivors.

The decision to deliver/terminate the pregnancy immediately or after expectancy depends on weighing the risks of leaving the surviving fetus in an intrauterine environment that may have caused the death of its co-twin and the possibility of serious morbidity with the neonatal risks associated with preterm delivery of the surviving fetus. In “dichorionic twin pregnancies” with the death of one twin, the outcome of the surviving twin is usually benign. In “monochorionic twins”, the timing of injury is thought to be at the time of intrauterine fetal death and not at the time of diagnosis or thereafter. It seems the balance is in favor of expectant management until risks of fetal prematurity are diminished.

**Twin-to-Twin Transfusion Syndrome**

Twin-to-twin transfusion syndrome is usually a complication seen in monochorionic twin gestations. The imbalance in the vascular flows results in one of the twins being smaller and oligohydranmniotic while the other is plerohoric and polyhydramniotic. Central nervous system lesions may be seen in both twins. The criteria for the antenatal diagnosis of TTTS include the following: monochorionic twin gestation with placental vascular anastomoses, same-sex fetuses, intertwin birth weight difference greater than 20%, polyhydramnios of the larger twin, oligohydranmnios of the smaller twin, and hemoglobin difference of more than 5 g/dL. Factors that determine perinatal outcome include the gestational age at diagnosis, the gestational age at delivery, and the severity of the disease, i.e. presence of hydrops fetalis. The overall perinatal survival rate ranges from 21% to 65%. The watershed for survival appears to be 28 weeks gestation for delivery.

One of the treatments for TTTS is serial amnioreduction of the recipient, polyhydramnionic twin. In one study with 13 twins, the fetal survival rate for the serial amnioreduction group was significantly higher than the expectantly managed group (69% vs 20%, respectively). Amnioreduction may be less effective when there are fewer superficial anastomosis in the placenta. Fetoscopic neodymium: yttrium aluminium garnet (Nd: YAG) laser occlusion of the superficial vascular communications between the fetoplacental circulations has been used successfully at very early gestations. In a recent multicenter trial with 173 patients with TTTS before 27 weeks, laser-treated group had a significantly higher successful pregnancy outcome (at least one surviving infant) than the amnioreduction treated group (83.2% vs 66.7%, respectively). Also, neurologic morbidity was significantly lower in the laser-treated group. Other options for treating TTTS include septostomy and selective feticide in exceptional cases.

**ROUTE OF DELIVERY**

The two main factors which determine the route of delivery of twins are the “fetal presentations and lie” and the estimated weights of the fetuses. In general, when the first twin is nonvertex (breech or transverse lie), the recommended mode of delivery is cesarean section. When the first twin is vertex and second is nonvertex, decision-making is less clear. Though the Term Breech Trial favors planned cesarean delivery over vaginal presentation, its results in reducing perinatal morbidity may not be applicable to the second twin. When the estimated weight of the second twin is less than 1,500 g, there is benefit from avoiding a vaginal delivery. The benefit may be limited when birth weights are greater than 1,500 g. Though the vertex-vertex twin pair has traditionally thought to be suitable for vaginal delivery, there has been an interesting review of the subject by Smith et al. They retrospectively studied 8,037 twin births and found that in the intrapartum period, there were six deaths of the first twin and 30 deaths of the second twin. They concluded that a planned cesarean section in vertex-vertex twins may reduce the perinatal morbidity by 75%. This has raised the question of whether all twin pairs should be delivered by cesarean section.

Time restriction for interdelivery interval is thought to be less important if there is continuous fetal monitoring and the pattern is reassuring. Though there was no difference in Apgar scores or birth trauma in twins delivered more than 15 minutes apart, there was a higher incidence of cesarean section for the second twin with delayed delivery.

**POSTNATAL ISSUES**

Breastfeeding would be ideal for twins as for singletons. However, the rates of successful breastfeeding initiation and continuation depend on the degree of motivation of the mother and the support (family and support groups)
available. The rates may be 80–90% in optimal conditions. However, in less than ideal situations, rates are closer to 40%. The factors that can improve breastfeeding success include counseling before delivery, support and motivation after delivery and training in specific techniques (double football hold, double cradle position, etc.). The approach should be one of sensitivity and understanding. One must realize that partial breastfeeding may also be beneficial.

Chapter 24

Preterm Premature Rupture of Membranes

**INTRODUCTION**
Preterm prelabor rupture of membranes (PPROM) is defined as rupture of membranes before onset of labor in a patient who has not completed 37 weeks of gestation.

**INCIDENCE**
Preterm prelabor rupture of membranes occurs in around 2% of all pregnancies and is associated with 30-40% of preterm deliveries.

**ETIOPATHOGENESIS**
An important etiological mechanism is infection; organisms implicated being *Chlamydia trachomatis,* group B *Streptococcus* and less pathogenic organisms, such as those involved in bacterial vaginosis.

Usually, rupture of fetal membrane is preceded by structural weakness associated with extracellular matrix degradation and cellular apoptosis, but a substantial proportion of cases are associated with chorioamnionitis.

Second-trimester elevated plasma thrombin, anti-thrombin complexes concentrations are predictive of subsequent PPROM which provides evidence that PPROM is also associated with decidual thrombin activation.

**RISK FACTORS**
Risk factors for prelabor rupture of membranes are previous preterm delivery (Odds ratio (OR) 2.8), early pregnancy bleeding (OR 2.4 for first trimester bleeding, OR 4.4 for second trimester bleeding) and cigarette smoking (OR 2.1).

Other clinical factors associated with PPROM include low socioeconomic status, low body mass index, tobacco use, urinary tract infection, cerclage and amniocentesis.

**MANAGEMENT**

**Diagnosis**
Prompt and accurate diagnosis is essential for optimal maternal and perinatal outcome. However, diagnosis may be difficult by any single method and is best made by an accurate history, careful examination and necessary investigations.

**History**
Most patients complain of a sudden gush of fluid from the vagina followed by persistent leakage. A detailed history regarding the time of membrane rupture, the color of the fluid (passage of meconium) and presence/absence of uterine contractions should be taken.

**Physical Examination**
A sterile speculum examination should be performed. If the fluid cannot be seen, the patients can be asked to cough or strain. If there is any doubt regarding diagnosis, the woman may be asked to wear a pad that can later be examined.

A digital examination is best avoided, if the patient is to be managed conservatively. Digital examination of the cervix with PPROM has been shown to shorten latency and increase...
risk of infections without providing any additional useful clinical information.

**Investigations**

The principle of investigations is to differentiate amniotic fluid from urine or cervical/vaginal secretions.

- **Nitrazine paper/Litmus test**: Amniotic fluid is alkaline with a pH of 7.5. Red litmus turns blue, and nitrazine paper, which is orange, also turns blue when it comes into contact with amniotic fluid. False positive reactions may occur due to vaginal infections.

- **Ferning**: Fluid from the vaginal pool is dried on a slide and examined under the microscope. Formation of a fern pattern suggests that the fluid is amniotic fluid.

- **Cytological methods for the detection of fetal cells in amniotic fluid**: When amniotic fluid is treated with Nile blue sulfate, fetal cells with a higher fat content take an orange color against a blue background. This test may not be reliable in very early PPROM as the percentage of fetal cells with fat is less.

- **Ultrasound** is valuable in assessing the amount of amniotic fluid, the gestational age and estimated birth weight.

- **Dye tests**: A dye like indigo carmine is introduced into the amniotic cavity. Leakage of the dye per vaginum confirms the diagnosis. This test is not commonly practiced as it may introduce infection and precipitate preterm labor.

**CONSEQUENCES OF PPROM**

The most common consequence of PPROM is preterm delivery. Irrespective of gestational age, a delay of more than one week will be achieved by less than half the women.

Infectious morbidity, mostly due to ascending intrauterine infection, is the second most important hazard for the baby.

Other consequences of PPROM include increased risks of pulmonary hypoplasia, especially with very preterm PROM, deformities associated with persistent oligohydramnios, placental abruption and cord prolapse.

**Prediction of Infection and Risk of Preterm Delivery in PPROM**

Chorioamnionitis is associated with maternal and neonatal sepsis and can become life-threatening. Presence of infection warrants immediate termination of pregnancy. Clinical features of infection are maternal or fetal tachycardia, maternal fever, uterine tenderness and foul smelling vaginal discharge. However, preclinical occult infection may be present, the detection of which is difficult.

Investigations, which should be performed, are complete blood count and C-reactive protein (CRP). Studies examining the use of CRP as a predictor of chorioamnionitis in PPROM report highly conflicting results. There is no clear evidence to support the use of CRP for the early diagnosis of chorioamnionitis.7

Lewis et al. performed a randomized clinical trial comparing daily non-stress testing with a biophysical profile in the prediction of infectious morbidity in patients of PPROM between 23 and 34 weeks of gestation. Their conclusion was that neither test had good sensitivity for predicting infectious complications.8

Interleukin-6 determinations in cervical fluid have diagnostic and prognostic value in PPROM.9 Amniotic fluid metalloproteinase levels are significantly elevated in women with intra-amniotic infection.10

Sonographic measurement of cervical length in pregnancies complicated by PPROM helps to distinguish between those women who deliver within 7 days and those who do not.11

According to a study done by Rizzo et al., the combined use of the amniotic fluid interleukin-6 assay and the cervical index in patients with PPROM provides a good prediction of the interval from admission to delivery, thus identifying a subgroup of patients at high-risk of imminent delivery.12

Cervical and/or regional fetal fibronectin levels can be done to predict the presence of upper genital tract infection. According to the preterm prediction study, women with a positive fetal fibronecin test who delivered before 32 weeks of gestation all had evidence of histologic chorioamnionitis. Women positive for fetal fibronectin had a 16-fold increase in clinical chorioamnionitis and a sixfold increase in neonatal sepsis.13

**MANAGEMENT OF PPROM**

There are many complex issues involved in the management. On the one hand, there is a fear of serious maternal morbidity and intrauterine infection and, on the other hand, there is apprehension about poor survival rates when delivery is necessary at early gestational age.

If a patient has evidence of intra-amniotic infection by clinical examination (maternal temperature greater than 38°C, fetal tachycardia, fundal tenderness, foul or purulent vaginal discharge, maternal tachycardia) or elevated CRP, amniocentesis shows positive Gram stain, glucose less than 20 mg/dL and amniotic fluid culture is positive for aerobic, anaerobic organisms or mycoplasma, then institution of broad spectrum antibiotics and delivery are necessary irrespective of gestational age.

If after initial evaluation of the mother and fetus, they are both determined to be clinically stable, expectant management of PPROM may be considered to improve fetal outcome.

**Antibiotics**

The initial step in management of PPROM is informed consent. The patient needs to be given risks and benefits information and must participate in decision making.
Two of the largest studies that have looked at the efficacy of antibiotic use in PPROM are the National Institute of Child Health and Human Development–Maternal Fetal Medicine Units (NICHD-MFMU) study of PPROM and the ORACLE trial. In the NICHD study, intravenous antibiotics were used for 48 hours—ampicillin 2 g q6h and erythromycin 250 mg q6h. The patients were then placed on oral amoxicillin 250 mg q8h and enteric-coated, erythromycin-base 333 mg every q8h to complete a 7-day course of antibiotic therapy. In this study, the control group, compared with the antibiotic group, had a significantly shorter duration of latency. The antibiotic group was twice as likely to remain undelivered after 7 days. The increased latency continued for up to 3 weeks after discontinuation of antibiotics. Composite and individual morbidities for the neonate were lower in the antibiotic group. The incidence of chorioamnionitis and neonatal sepsis, including group B streptococcal sepsis, was decreased.14

The ORACLE trial used erythromycin alone, amoxicillin with clavulanic acid alone or amoxicillin with clavulanic acid in combination with erythromycin. Their results were different in that no significant difference was noted in latency to delivery and neonatal morbidity was not decreased as defined in their primary outcome (death, chronic lung disease and major cerebral abnormality on ultrasonography). Decreased need for supplemental oxygen and positive blood culture results were apparent. When amoxicillin with clavulanic acid was used either alone or in combination with erythromycin, an increased risk of necrotizing enterocolitis (1.9% versus 0.5%, p = 0.001) was present.15

The authors of ORACLE also concluded that antibiotics should not be routinely prescribed to women in spontaneous preterm labor without clinical evidence of infection.16 Based on current evidence, 7 days of antibiotics, as proposed by the NICHD-MFMU study of PPROM, should be the antibiotic regimen used in patients with PPROM who are being managed expectantly. Therapy longer than 7 days should be avoided. It has not been shown to be more effective and may promote the emergence of resistant organisms.

Antenatal Corticosteroid Treatment

The use of corticosteroids to accelerate lung maturity should be considered in all patients with PPROM with a risk of infant prematurity from 24 to 34 weeks of gestation.17

The use of steroids has also been suggested to increase the risk of infection. However, the current evidence does not support this concern based on individual studies and meta-analyses; no difference (either higher or lower rates of infections) has been observed with corticosteroid use. In contrast to these concerns, data indicate that the use of corticosteroid reduces neonatal morbidity and mortality. The rates of respiratory distress syndrome (RDS), necrotizing enterocolitis and intraventricular hemorrhage were all lower when either 12 mg of betamethasone intramuscular was given twice in a 24-hour interval or dexamethasone 6 mg q12h was given for four doses.

The National Institutes of Health consensus panel also recommends the use of corticosteroids prior to 30–32 weeks in absence of chorioamnionitis.17

Role of Tocolytics

Tocolytics may be used to prolong gestation long enough to complete a course of steroids and for in utero transfer; chorioamnionitis being a strict contraindication. However, studies have failed to prove that tocolysis in patients with preterm premature rupture of membranes significantly improves the perinatal outcome.18

Antenatal Fetal Surveillance

A number of biophysical parameters have been used to predict infection. Fetal breathing activity is reduced after preterm PPROM and a number of groups have documented an association between subsequent sepsis and reduced breathing; however, some recent evidence seems to challenge this.8

Direct ultrasonographic measurement of fetal lung length in normal pregnancies and pregnancies complicated by prolonged rupture of membranes was found to be predictive of fetal pulmonary hypoplasia.20 However, recent studies have found that fetal lung length determined by ultrasound does not predict adverse neonatal respiratory outcome and that the prediction of pulmonary hypoplasia in livebirths after prolonged PPROM remains an elusive goal.21

Care must be taken during the expectant management of patients with nonvertex presentation. In a study by Lewis et al., patients with PPROM with non-vertex presentations appear to have a significantly higher risk for prolapsed umbilical cords, lower Apgar scores and/or lower umbilical cord blood pH values, when compared with their vertex counterparts. Additionally, there appears to be substantial risk of an unintended vaginal breech delivery.22

PPROM at Early Gestation

Loss rates are dependent on the gestational age at which PPROM occurs. Second trimester PPROM usually carries a dismal prognosis. In gestational ages less than 24 weeks, risk of chorioamnionitis is high (30–60%) and pulmonary hypoplasia exceeds 50%. In a study by Taylor, following PPROM at a gestational age of 23 weeks, only 10% of pregnancies produced a neurologically normal, long-term survivor.23

In these cases, maternal well-being should be the utmost concern and therapeutic termination of pregnancy is an option. Pulmonary hypoplasia is dependent on gestation at membrane rupture. Prediction is difficult but nomograms of chest circumference or lung length may help.
It is important to arrange for in utero transfer to institutions with a well-equipped neonatal intensive care unit at early gestation.

Management of Patients Who have a Cervical Cerclage Stitch and Subsequently Develop PPROM

The optimal management of PPROM in a patient with a cerclage is controversial. The issues are whether the latency period between rupture of membranes and delivery is decreased, if the cerclage is removed and whether there is an increased rate of maternal or neonatal infection if the cerclage is kept in place. Latency seems to be increased if the cerclage is kept in place, but maternal and neonatal infectious morbidity is also increased. In women at early gestational ages, keeping the cerclage in place may be warranted until labor ensues. In more advanced gestations, it seems preferable to immediately remove the cerclage upon diagnosis of PPROM.24

Role of Amnioinfusion

Although there have been several studies evaluating the value of amnioinfusion for PPROM, according to the recent Cochrane review, there is not enough evidence concerning the use of amnioinfusion for preterm rupture of membranes.25

SUMMARY AND KEY POINTS

- PPROM is a common complication of pregnancy occurring in about 3% of all pregnancies.
- Diagnosis needs to be confirmed.
- Digital vaginal examinations should be avoided.
- Ultrasonography should be performed to confirm gestational age, estimated fetal weight, presentation, amniotic fluid index and fetal anatomy if not already fully evaluated.
- Antibiotics should be given based on present evidence.
- Informed consent should be obtained for expectant management versus delivery with careful documentation in the chart.
- Maternal health is the primary indicator for the need to deliver. Any evidence of infection or maternal instability due to complications of PPROM, such as bleeding, requires careful evaluation and determination of the appropriateness of expectant management.
- Fetal monitoring should be performed at least daily until delivery, and fetal well-being and growth should be evaluated periodically with ultrasonography.
- After 32 weeks and certainly after 34 weeks of gestation, the appropriateness of expectant management of PPROM should be reevaluated individually for each case.
- The overall goal is to manage the patient expectantly until she has reached a gestational age beyond which neonatal morbidity and mortality is minimal and to deliver her before she and her fetus becomes infected.

Current Trends in the Management of Preterm Labor

INTRODUCTION

Preterm birth continues to be one of the most important obstetric problems in the world, contributing to nonanomalous perinatal mortality ranging between 38% and 52%. The perinatal mortality among preterm Indian babies has been reported to be two to seven times higher than among babies born at term. Preterm birth complicates 5–10% of pregnancies, and is the leading cause of perinatal mortality and morbidity. The problem of neurological handicap in groups below 34 weeks has decreased considerably in the western countries. The same cannot be said of the developing countries; one has to think in terms of instituting more neonatal intensive care units, which at present are limited to a few tertiary centers. Therefore, the solution lies in improving antenatal care to prevent preterm labor (PTL) or refer such cases to institutions where expert care is available.

ETIOLOGY

Preterm labor is essentially multifactorial in origin. The pathophysiology of PTL is shown in Flow chart 1. Before instituting measures to prevent it, placental abnormalities, uterine anomalies, uterine overdistention and fetal mallformations should be ruled out. The philosophy of management of these cases is in a different direction, except for placenta previa. Other factors, which influence the occurrence of PTL, are as follows:

- **Infections:**
  - Intrauterine, both overt and subclinical (20–30%), caused by *Ureaplasma urealyticum*, *Bacterial vaginosis*, *group B Streptococcus* (GBS), *Escherichia coli*, *Bacteroides* sp., *Mycoplasma hominis*, *Fusobacterium* sp., *Listeria monocytogenes*, *Lactobacillus* sp., *Peptostreptococcus* sp. and *Chlamydia trachomatis*.
  - Extrauterine (5–10%), urinary tract infection (UTI), asymptomatic bacteriuria (ASB), GBS, trichomoniasis.

- **Inflammatory:** Mainly due to infection, redundancy in cytokine network, decreased production of interleukin-10 (IL-10).

- **Stress**

- **Inadequate expansion of plasma volume during pregnancy**

- **Withdrawal (suspension) of progesterone action**.

EPIDEMIOLOGY

The epidemiologic picture of women at risk for preterm delivery is influenced by infections, nutrition and sociodemographic factors like age, race, socioeconomic status and physical labor. The preterm delivery rate in blacks is approximately twice as that in whites, 16.3% as against 7.7%. The incidence of PTL is inversely related to the socioeconomic status. Other maternal characteristics, which influence the occurrence of PTL, are maternal prepregnant weight (< 51 kg), age, smoking, occupations requiring prolonged standing, long hours of work and physical labor. From an obstetrical point of view, factors which contribute significantly are: a weight gain of less than 11 kg or more than 13 kg during index pregnancy, and a previous history of abortions or PTL. Pregnant mothers who do heavy physical work are at an
increased risk (25% more) of developing PTL than those who do light work.11

The role of coitus in precipitating PTL has been debatable. Factors, which are believed to be responsible for PTL, are the prostaglandins present in seminal fluid, prostaglandin release during orgasm and ascending amniotic fluid infection.12

**IDENTIFYING WOMEN AT RISK OF PRETERM BIRTH**

Based on the epidemiologic factors mentioned above, various scoring systems have been developed to identify the women at risk of PTL. These scoring systems also take into account past and index pregnancies. Risk factors identify some women destined to go into PTL but they have been found to have a sensitivity of around 50%. Therefore, the usefulness of such scoring systems is limited. However, the risk of PTL in women with previous one and two preterm delivery is 17.2% and 28.4%, respectively.13 It should be remembered that the same level of surveillance is required for all pregnancies no matter how low the risk may be. Further the risk of recurrent PTL varies considerably by fibronectin status and cervical length, from less than 10% when the cervix is longer than 35 mm and the fibronectin is negative, to more than 60% when the cervix is shorter than 25 mm and the fibronectin is positive.14
DIAGNOSIS OF PTL

The importance of warning symptoms like dull low backache, abdominal cramping and mucous vaginal discharge prior to established PTL cannot be overemphasized.

According to Herron et al., the diagnostic criteria for PTL are as follows:15

- Gestational age between 20 weeks and 37 weeks
- Regular uterine contraction 5–8 minutes apart or less, accompanied by one or more of the following:
  - Progressive changes in the cervix
  - Cervical dilatation of 2 cm or more and cervical effacement of 80% or more.

Threatened PTL is the presence of uterine contractions with formation of the lower segment but with no definite cervical change.

EVALUATION OF PTL

The objectives of evaluation of a patient with threatened or established PTL are to:

- Confirm the diagnosis
- Identify the cause, if possible
- Estimate the period of gestation (in developing countries, the period of gestation should be at least 28 weeks)
- Plan intervention.

After obtaining a thorough obstetric and medical history and performing a complete physical examination, an ultrasonographic examination should be performed to assess the gestational age, the amniotic fluid volume and fetal weight to locate the placenta and to rule out fetal anomalies.

Transvaginal Sonography

It is useful in determining the cervical length and dilatation. At 24 weeks of gestation, the cervical length is about 35 mm and those with progressively shorter cervices experience increase in rate of preterm birth.16

The progressive changes in the cervix are shown in Figure 1.

INVESTIGATIONS

It is important to investigate a case thoroughly and detect the underlying etiology. The results of investigations also help one to evaluate the benefits of medical or surgical intervention. The following investigations are indicated:

- Hemogram including complete blood count and differential count
- Urinalysis and culture
- Serum C-reactive protein (chances of PTL if > 0.8)
- Glucose and creatinine levels
- Electrocardiogram if over 30 years old
- Cervicovaginal fluid for culture and sensitivity and fetal fibronectin levels18

Fig. 1: Representing the cervical changes seen on transvaginal sonography where T, Y, V, U denote the relationship between the lower uterine segment and the cervix17

- Amniocentesis for evidence of chorioamnionitis
- Amniocentesis should be performed in women with PTL whenever amnionitis is suspected, e.g. unexplained maternal fever, leukocytes, fetal tachycardia or uterine contractions which are difficult to arrest with standard doses of tocolytics
- Biochemical markers: Evaluation of activin, inhibin and relaxin may have a role in predicting PTL.19
- Cervical effacement of 80% or more, dilatation more than 2 cm, increase in dilatation of 1 cm or more, sonographic cervical length under 30 mm, or a positive fibronectin level should be documented before the diagnosis of PTL is accepted.14

TREATMENT OF PRETERM LABOR

Bed rest, especially in the left lateral position, is an accepted modality in the treatment of PTL. Administration of intravenous (IV) fluids further improve the outcome. Valenzuela et al. in their series, reported that 50% of patients responded to this therapy.20

The importance of tocolytic agents in threatened or established PTL cannot be overemphasized. Various tocolytics have been used with success rates varying from 40% to 90% (Table 1).

Tocolysis

It has been well established that tocolysis improves perinatal mortality and morbidity due to preterm birth. An ideal tocolytic drug would be one which produces tocolysis without any maternal or fetal side-effects. Such an agent is yet to be identified. Historically, various hormones, psycholeptics,

**Side effects:**
- Maternal: Palpitations, tremors, anxiety, migraine, chest pain, pulmonary edema, hypoglycemia, paralytic ileus
- Fetal and neonatal: Inconsistent FHR changes, fetal acidosis, fetal hypoglycemia, sometimes neonatal relative hypoglycemia

**Contraindications:**
- Heart block, myocardial damage, compromised renal function, myasthenia gravis
- Hypothyroidism, sickle cell disease, patients on MAO inhibitors, asthmatics on beta-adrenergics

**Abbreviations:**
- TID, thrice a day; QID, four times a day; q20m, every 20 minute; q6h, every 6 hour; MgSO$_4$.7H$_2$O, magnesium sulfate; q10m, every 10 minute; q2-4h, every 2–4 hour; q3-4h, every 3–4 hour; q4h, every 4 hour; FHR, fetal heart rate; bpm, beats per minute; MAO, monoamine oxidase; q2h, every 2 hour; q3-6h, every 3–6 hour
sedatives, vasodilators and neuromuscular agents have been used to arrest PTL. Progesterone has not been proven to be an effective inhibitor of PTL. IV infusion of ethanol has fallen into disrepute because of the maternal side-effects like nausea, vomiting, headache, restlessness and also due to the fetal withdrawal syndrome. Tocolytic agents are generally contraindicated in the following situations:

- **Maternal**: Hypertension, cardiac disease, placental abruption, hypothyroidism, uncontrolled diabetes, chorioamnionitis, eclampsia, severe anemia and cervical dilatation more than 3 cm
- **Fetal**: Demise, severe intrauterine growth restriction, lethal anomalies and distress.

Tocolytic agents currently employed, their efficacy, dosage, administration and the mode of action is shown in Table 1 and Flow chart 2, respectively.

**Other Drugs which have been Used in the Management of Preterm Labor**

**Prostaglandin Synthetase Inhibitors**

Prostaglandins act by increasing the myometrial gap junctions and enhanced calcium release from intracellular stores, thus resulting in uterine contractions (Flow chart 1). Prostaglandin synthetase inhibitors act by inhibiting the action of cyclooxygenase enzyme which results in decreased prostaglandin synthesis. Indomethacin and more recently mefanemic acid, have been used as tocolytic agents. Prostaglandin synthetase inhibitors cause maternal gastrointestinal upset, drug rash and rarely bleeding disorders. In the fetus, indomethacin causes constriction of the fetal ductus arteriosus and decreased urine output leading to oligohydramnios. Therefore, indomethacin is advocated only before 32 weeks of gestation.

**Nitroglycerine**

Nitroglycerine is a donor of nitric acid, and can be applied in the treatment of PTL. Nitric oxide is an endogenous compound relaxing nonstriated muscles. In the uterine-placental unit, it acts synergistically with progesterone-inhibiting uterine contractility. It is a safe, well-tolerated, noninvasive method of tocolysis which is used as patches.

**Oxytocin Antagonists**

Oxytocin antagonists are peptides that block the action of endogenous oxytocin by effectively competing for the finite number of myometrial cell oxytocin receptors and by blocking the production of inositol triphosphate (IP3) receptors. An oxytocin antagonist, l-deamino-2-D-Tyr (Oet)-4-Thr-8-Orn oxytocin was used in a pilot study by Akerlund and associates. More recently, the use of atosiban at doses of 300 µg/min as an IV infusion for 2 hours has been reported.
Precautions

Tocolytic agents are potent drugs with abundant possibilities for serious complications and therefore, complaints of side-effects should never be ignored. Complications are more likely to occur in multiple gestation, maternal anemia, occult amnionitis or occult placental abruption, undiagnosed maternal heart disease, prolonged parenteral infusions of tocolytics for more than 24 hours, maternal age more than 30 years, combination therapy with multiple tocolytics and in those receiving steroids. A very careful attention to fluid balance is required, and a pretreatment electrocardiogram is a reasonable precaution. If amnionitis is ruled out, infusion can be continued for 12–24 hours. After 24 hours, it is prudent to start oral tocolytics with careful surveillance for another episode of PTL.

In order to avert the side-effects of the tocolytic drugs, acupuncture has been tried and found to be effective in the arrest of PTL.\textsuperscript{33}

Progesterones

Progesterone has been shown to prevent the formation of gap junctions and to have inhibitory effect on myometrial contractions. 17 alpha-hydroxyprogesterone caproate is injected in the dose of 250 mg intramuscularly on weekly basis till 36 weeks of gestation. Studies have shown that progestational agents did not increase the risk of spontaneous abortions, fetal congenital malformations, perinatal or neonatal morbidity or mortality.\textsuperscript{44}

Antibiotics

Earlier various studies showed that PTL was due to infection. Antibiotics were being used in many centers for treatment of PTL. In a randomized double-blind placebo-controlled trial, there was no statistically significant difference between clindamycin and placebo-treated groups.\textsuperscript{45} Norman et al. concluded from a multicentric, randomize controlled trial that a combination of ampicillin and metronidazole when given to women with PTL significantly prolongs pregnancy.\textsuperscript{36} However, it seems more logical to administer antibiotics to women at risk of PTL with infections proved by culture from a high vaginal swab or of amniotic fluid. The risk of PTL was successfully decreased from 40% to 25% in mothers treated with either metronidazole or erythromycin who had evidence of bacterial vaginosis.\textsuperscript{37}

Presently antibiotics for PTL with intact membranes are recommended when there is evidence:

\begin{itemize}
  \item Of chorioamnionitis
  \item Gestational age is less than or equal to 28 weeks
  \item Failure of tocolysis (before beginning a second tocolytic agent).\textsuperscript{48}
\end{itemize}

Steps to Reduce Neonatal RDS and IVH

Maternal administration of corticosteroids to promote fetal pulmonary maturity should be considered if the period of gestation is between 28 weeks and 32 weeks. The most extensively used regimens are two doses of betamethasone 12 mg given intramuscularly 24 hours apart, or four doses of dexamethasone given intramuscularly 12 hours apart. Because of insufficient scientific data from randomized control trials regarding safety and efficacy, repeated courses of steroids should be used.\textsuperscript{49} More recently, other strategies have been employed to reduce respiratory disease in premature infants. Maternal administration of thyrotropin-releasing hormone (TRH) elevates prolactin and thyroxin in the fetus, and has reduced the incidence of bronchopulmonary dysplasia. Preliminary reports are encouraging.\textsuperscript{50} The other agent, inositol, a component of membrane phospholipids has been supplemented to preterm infants with respiratory distress.\textsuperscript{51} Artificial surfactant therapy in the preterm neonate has been found to decrease the severity of RDS.

RISK TO THE NEONATE

Once the preterm baby is born, it is prone to a large number of complications which are as follows:\textsuperscript{13}

Immediate

\begin{itemize}
  \item Birth asphyxia
  \item Respiratory distress syndrome (RDS)
  \item Jaundice
  \item Hemorrhage
  \item Hypoglycemia
  \item Hypocalcemia
  \item Sepsis
  \item Feeding difficulties
  \item Necrotizing enterocolitis
  \item Patent ductus arteriosus
  \item Intraventricular hemorrhage (IVH)
  \item Iatrogenic-induced complications, e.g. retrolental fibroplasias
\end{itemize}

Late

\begin{itemize}
  \item Sensorineural deafness
  \item Developmental delay
  \item Reduced growth potential
  \item Recurrent respiratory infections
  \item Learning difficulties
  \item Social: Enforced separation of mother and baby
  \item Sudden infant death syndrome (SIDS)
  \item Blindness
  \item Child abuse
\end{itemize}

Antibiotics for PTL with intact membranes are recommended when there is evidence:

\begin{itemize}
  \item Of chorioamnionitis
  \item Gestational age is less than or equal to 28 weeks
  \item Failure of tocolysis (before beginning a second tocolytic agent).\textsuperscript{48}
Phenobarbital when given to mothers in established PTL at doses of 10 mg/kg IV over 30 minutes (500 mg minimum and 700 mg maximal dose), has been shown to prevent intraventricular bleeding in the newborn. Maternal administration of vitamin K reduces the incidence and severity of IVH in the neonate.

**IN UTERO TRANSFER**

One of the most important questions facing the obstetrician is whether or not to transfer the mother to a center where intensive neonatal care facilities are available. The survival of premature infants in neonatal intensive care units considerably exceeds those in institutions without such facilities. In developing countries where very few hospitals are equipped to take care of premature infants, it is advisable to refer the women at risk of PTL to tertiary care centers. Such referrals should be withheld if there is a strong likelihood of mother delivering in transit.

**INTRAPARTUM MANAGEMENT**

A close intrapartum surveillance is of paramount importance in PTL because intrapartum asphyxia increases the incidence of RDS and IVH. Electronic fetal heart rate (FHR) monitoring and fetal scalp pH measurement should be used liberally. Borderline pH values of 7.20–7.25 require prompt correction. These babies are likely to become asphyxiated early in labor. If cardiotocography is not available, auscultation of the fetal heart must be performed at 15-minute interval, especially during and soon after contractions. In delivering the preterm fetus, Cesarean section confers certain benefits like avoiding birth trauma, asphyxia and reduced incidence of IVH. If the lower uterine segment is thick and not well formed, it may be prudent to give a lower vertical incision. In developing countries, Cesarean section does not appear to be beneficial in the long run, especially when the gestational age is less than or equal to 32 weeks as expert neonatal care is always available.

In delivering the preterm baby vaginally, the routine use of forceps has become questionable since the work of Fairweather and Stewart. Elective liberal episiotomy has been advocated with a view to shorten the second stage of labor and to reduce the force compressing the soft fetal skull. It is now recognized that ventouse extraction of the preterm fetus may be harmful.

**PREPREGNANCY PREVENTION OF PRETERM BIRTH**

Proper counseling to discourage induced abortion, early detection and treatment of uterocervical anomalies and treatment of UTIs contribute to prevention of preterm birth. Social intervention with a view to eliminate risk factors like malnutrition, anemia, smoking and vaginal infections can to a great extent prevent preterm birth.

Developed countries like Singapore, Sweden and France have recorded a dramatic decline in the incidence of prematurity. This reduction of prematurity rate from 12% to 6.5% in Singapore was achieved by socioeconomic change, decreased fertility and improved health care.

**CONCLUSION**

In India, preterm births account for a sizeable number of perinatal deaths largely due to lack of neonatal intensive care units in most hospitals. Therefore, there is a need to identify the women at risk of PTL and institute intervention early in labor. A variety of potent tocolytic agents are now available, those with least maternal side-effects and those that do not cross over to the fetus must be selected. Efforts should be made to develop good referral networking for neonatal intensive care. The need to institute social intervention and improve reproductive health care cannot be overemphasized. A change in the attitude of the obstetrician toward the problem of preterm birth is necessary. Once the obstetrician is genuinely convinced, then many strategies to battle against prematurity become possible.

**REFERENCES**

INTRODUCTION

Perinatal deaths due to Rhesus (Rh)(D) alloimmunization have fallen 100-fold, since the introduction of anti-D immunoglobulin (IG) in 1969.\(^1\) Use of anti-D in Rh(D) negative women after sensitizing events during pregnancy and after birth of a Rh(D) positive infant has created a major impact on this disorder.

In India, a recent perinatal audit found the incidence of perinatal deaths due to Rh alloimmunization to be, between 1% and 2.5%.\(^2\) Postpartum administration of Rh(D) immunoglobulin (RhIG) was highly successful because most of the instances of alloimmunization are due to the exposure of the mother’s immune system to Rh antigen by the transplacental passage of fetal Rh(D) positive cells during labor and delivery. Unfortunately, in some cases sensitization can occur during pregnancy due to “silent bleeds”. In these cases, postpartum administration of RhIG is ineffective as Rh sensitization has already occurred. At a conference convened by the Royal College of Physicians of Edinburgh and Royal College of Obstetricians and Gynaecologists,\(^3\) the panel reached the conclusion that Rh(D) alloimmunization still occurs due to two main reasons:

1. Some women do not receive the benefit of the recent policy
2. Women are sensitized by small bleeds from the fetus, mainly in the last 12 weeks of pregnancy, which may go undetected.

Majority of the cases seen today are due to the under utilization of RhIG.

The following obstacles need to be addressed:

- Insufficient awareness of antenatal injection of Rho(D) immunoglobulin (RhIG)
- Controversies in certain situations like presence of vesicular mole or after surgical sterilization in women
- Uncertainty of dosage to be given after cesarean delivery
- Cost-effectiveness
- Widespread education on effective prevention
- Commitment to eradicate hemolytic disease of the newborn (HDN)
- Safety of prophylaxis
- Adequate supply
- Compliance with guidelines for treatment.

Effective elimination of Rh-isoimmunization will be a result of overcoming various problems with a combination of different options available to us.

Present day practice mandates a more aggressive utilization of antibody mediated immune suppression, in order to achieve a lower incidence of Rh disease.

Identifying Candidates for Immunization

On the first prenatal visit, ABO grouping, Rh typing and antibody screening should be performed to identify the requirement of RhIG. The mate of the Rh negative pregnant woman should also be tested, because if both partners are Rh negative, there is no need for Rh immunoprophylaxis. However, if there is any doubt about the identity of the father, the mother remains a candidate for anti-D prophylaxis. If the woman is found to be Rh negative and is not actively producing anti-D, she is a candidate for RhIG prophylaxis later in the pregnancy. She should be counseled at this time regarding
the need for prophylaxis and the possible dosage schedule and timing of administration of RhoIG. The laboratory should also perform a test for D<sup>o</sup> on all Rh(D) negative prenatal patients. D<sup>o</sup> positive individuals should be considered as Rh positive provided the D<sup>o</sup> control is negative. A positive D<sup>o</sup> test, indicates that the patient’s red cells possess a variant of the Rho(D) antigen and may be considered Rh positive. However, there is a potential for misinterpretation of positive D<sup>o</sup> test results in late pregnancy and at delivery due to the presence of fetal cells in the maternal circulation.

A noninvasive prenatal determination of the fetal Rh(D) status might be useful for the management of pregnancies in Rh(D) negative women whose partners are Rh(D) positive. Studies by Di Simone N et al. have found false positive results for Rh(D) in polymerase chain reaction (PCR) of deoxyribonucleic acid (DNA) obtained from maternal plasma. Based on these studies, flow cytometric analysis might be proposed as a clinical tool for the noninvasive prenatal determination of the fetal Rh(D) status independently of fetal gender.<sup>3</sup>

**ANTEPARTUM PROPHYLAXIS**

**Rationale for Antepartum Administration of Rh-immunoglobulin**

The most important cause of anti-D antibodies is now immunization during pregnancy where there has been no overt sensitizing event. Although most of the Rh sensitization occurs after delivery, the most common time Rh positive red cells from the baby enter the mother’s circulation about 15% are caused by small fetomaternal hemorrhages that occur between 20 weeks and 40 weeks. Until the present there has been a gap in the coverage and protection, because the protocols were outlined only for the postpartum period. By covering this group it is possible to reduce the immunization rate from 1.5% to 1.8%, following only postpartum prophylaxis to almost zero.

The risk of Rh(D) alloimmunization during or immediately after a first pregnancy is about 1.5%.<sup>4</sup> Administration of 100 μg [500 International units (IU)] anti-D at 28 weeks and 34 weeks of gestation to women in their first pregnancy can reduce this risk to about 0.2% without, to date, any adverse effects. Although, such a policy is unlikely to confer benefit or improve outcome in the present pregnancy, fewer women will have Rh(D) antibodies in their next pregnancy. Adoption of such a policy will need to consider the costs of prophylaxis against the costs of care for women who become sensitized and their affected infants, and local adequacy of supply of anti-D gammaglobulin. Two eligible trials, which involved over 4,500 women, compared anti-D prophylaxis with no treatment.<sup>4</sup> Although the data suggested, when women receive anti-D at 28 and 34 weeks of gestation, a reduced incidence of immunization during pregnancy [odds ratio (OR) = 0.44, 95% confidence interval (CI), 0.18–1.12], after the birth of a Rh positive infant (OR = 0.44, 95% CI, 0.18–1.12), and within 12 months after birth of a Rh positive infant “OR = 0.44, 95% CI, 0.19–1.01,” none of these differences were statistically significant. In the trial, which used the larger dose of anti-D (100 μg; 500 IU), there was a clear reduction in the incidence of immunization at 2–12 months following birth in women who had received Anti-D at 28 and 34 weeks (OR = 0.22, 95% CI, 0.05–0.88). No data were available for the risk of Rh(D) alloimmunization in a subsequent pregnancy. No differences were observed in the incidence of neonatal jaundice.

Late immunization during a first pregnancy is responsible for 18–27% of cases. Immunization during a second or subsequent pregnancy probably accounts for a similar proportion of cases, although in this situation it is impossible to distinguish late sensitization from failure of prophylaxis at the end of the preceding pregnancy.<sup>5</sup>

**Indications for Antepartum Use**

There was widespread acceptance of the principle of antibody mediated immune suppression, which was adopted into routine obstetric management of the mother “at-risk” of Rh(D) sensitization. It is now common practice to give passive immunization during the antepartum period in the following clinical situations:<sup>6,7</sup>

- Invasive prenatal diagnosis (chorion villus sampling, amniocentesis, fetal blood sampling)
- Other intrauterine procedures (insertion of shunts, embryo reduction)
- Antepartum hemorrhage, threatened, inevitable and induced abortion
- Ectopic pregnancy
- External cephalic version of the fetus
- Closed abdominal injury
- Intrauterine death.

**Dosage and Timing of RhoIG Injections**

To be successful, the proper amount of RhoIG must be administered prior to Rh sensitization. Thus, dosage and timing of injections are critical. The various indications and recommended doses for RhoIG administration to obstetric patients are summarized in Table 1.

**Uncomplicated Pregnancy (Routine Antenatal Prophylaxis)**

Pioneering studies from Canada by Bowman have suggested that antenatal administration of 300 mcg of RhoIG at 28–30 weeks of gestation to the pregnant unimmunized Rh negative woman is very effective in preventing Rh immunization. This is now the accepted standard of obstetric care in North America.<sup>9</sup>
Recommended dose (mcg)

- First trimester induced or spontaneous abortion: 50 mcg
- First trimester ectopic pregnancy: 50 mcg
- Second trimester induced or spontaneous abortion: 300 mcg
- Second trimester ectopic pregnancy: 300 mcg
- Second trimester amniocentesis: 300 mcg
- Prophylaxis at/about 28 weeks: 300 mcg
- Third trimester amniocentesis: 300 mcg
- Antepartum fetomaternal hemorrhage (accompanying abdominal trauma, abruptio placenta, unexplained fetal death, and placenta praevia, etc.): As determined by quantification of fetal red cells in aternal circulation (300 mcg will suppress the maternal response to 15 mL of packed red cells)

A multicenter trial of antepartum low-dose anti-D (50 mcg) was undertaken in United Kingdom (UK) to test the efficacy of a lower dose of anti-D Ig than that used in earlier studies. It was concluded that, while two doses of 250 IU (50 mcg) anti-D may reduce alloimmunization, they are not as effective as two doses of 500 IU (100 mcg). On the basis of a theoretical calculation based on the half life of gammaglobulin, it is expected that a single injection of 300 mcg of RhIG at 28 weeks provided protection for 12 weeks or 84 days. Therefore, antepartum prophylaxis with a single injection at 28 weeks was implemented, as described by Bowman. This would cover most pregnancies until delivery.

Delayed Pregnancy

A second injection of RhIG should be administered, whenever a patient progresses in pregnancy more than 12 weeks beyond the date of initial RhIG administration. For instance, if a patient has received an injection of RhIG at 28 weeks and does not deliver by 40 weeks, she should receive a second 300 mcg injection as soon, after 40 weeks, as possible. In this case, if delivery occurs within 3 weeks of the second injection and if there is no fetometal hemorrhage (FMH) in excess of 15 mL of red cells, a third administration after delivery can be withheld.

First Trimester Pregnancy Wastage

A 50 mcg dose (micro-dose) is considered adequate to prevent sensitization in patients whose pregnancies are terminated prior to 13 weeks of gestation. This prophylaxis is important since Rh antigen expression has been demonstrated on erythrocytes of early embryos (0.5 cm and 7 g in weight). The rate of Rh-alloimmunization after abortion is 5–10%, without prophylaxis. The risk increases with the gestational age of the abortus from nil at 4 weeks to 2% at 8 weeks, to 9% at 12 weeks or more. The method of termination of pregnancy also affects the risk. Various studies have suggested that fetal cell leak is higher in induced abortions as compared to spontaneous abortions. However, a policy adopted by many physicians is—when in doubt, it is better to give, rather than withhold RhIG.

Antepartum Fetomaternal Hemorrhage

When significant antepartum FMH is suspected for any reason, such as abruptio placentae, abdominal trauma, unexplained fetal demise or placenta previa, the dosage of RhIG should be determined after estimating the FMH. One 300 mcg dose of RhIG should be administered for each 30 mL of fetal whole blood or 15 mL of packed red cells.

POSTPARTUM PROPHYLAXIS

The risk of postpartum immunization increases with the amount of FMH (Table 2). This is because the prevalence of primary alloimmunization is antigen dose-dependent. However, this does not hold true for a secondary immune response, where the mother was already exposed to the Rh antigen in the past. In such cases, after doses as little as 0.05 mL of Rh positive cells, the immune response is stimulated. As discussed above, the risk of alloimmunization at 6 months postpartum is about 85%. However, due to “sensitization”, i.e. undetectable antibody levels until a secondary immune response is mounted, another 8% show Rh alloimmunization subsequently. Hence, the risk is about 16% for the first Rh positive ABO compatible pregnancy.

Studies have found that 75% postpartum women have 0.1 mL of fetal cells in their circulation and only 3% have 15 mL of fetal cells in the circulation. Hence, 300 mcg of RhIG is adequate for 15 mL of fetal cells or 30 mL of whole blood, is sufficient to prevent immunization in a majority of patients. Mollison had reported that 99% of postpartum women have 3 mL of FMH. Hence, a dose of 100 mcg may be adequate for most women as it is sufficient to clear 4 mL of red blood cells (RBCs).

In Great Britain, a dose of 500 IU (100 mcg) Rh anti-D IG is given to all Rh negative mothers who deliver a Rh positive infant unless the mother has already made anti-D antibodies,
which has been stimulated either by a previous pregnancy or by transfusion. These dosage principles were reviewed by a consensus panel in the UK, and were recommended by them as the reference standard for good clinical practice.18

In Australia, the standard dosage of anti-D currently, given at all gestational ages is one ampoule containing 125 µg of anti-D. This dose is supplemented when needed on the basis of maternal Kleihauer testing. Certain workers19 have suggested that this protocol should be revised for early pregnancy, using only 30 mcg, which would remove the entire fetoplacental blood volume (3 mL) of a 12 weeks of pregnancy from the circulation.

In India, the usual dose recommended is 300 mcg postpartum, keeping in mind practical problems of assessing FMH and ensuring subsequent adequate dosing. A study at a large population based Rh clinic in Mumbai has shown that the incidence of Rh negativity was 5% in pregnancy.20 The rate of Rh alloimmunization in Rh negative pregnant women declined from 0.16% in 1981–83 to 0.09% during 1990–92. The overall rate in Rh negative women in the clinic, pregnant and nonpregnant also declined from 3.1% to 1.7%. In India, anti-D IG was mainly used postpartum. Hence, a more comprehensive Rh prophylaxis program, would be needed to eradicate Rh HDN. 1.5–1.8% of Rh negative women become immunized in spite of routine postpartum Rh immune prophylaxis, probably due to immunization occurring during pregnancy.

A retrospective audit has a recommended reduction in the recommended routine postpartum dose of anti-D from 625 IU to 250 IU when flow cytometric quantitation for FMH is available, should be considered. Adopting such a strategy would ensure the ongoing provision of a valuable human blood product currently in limited supply.21

**Apparent Failures of Prophylaxis**

Jennings showed that most of the so-called, failures of prophylaxis were the result of immunization during pregnancy.22 This was supported by immunological evidence of the clinical trials, where only 6.91% of controls (who did not receive prophylaxis) became immunized at 6 months as compared to 12.92% at the end of the second pregnancy. This illustrated the "booster" effect of the next pregnancy on the so-called "sensibilization" phenomenon first described by Nevalinna.23 This phenomenon describes how some women can become primed, but their immune response remains occult until revealed by a subsequent exposure to the Rh-antigen.

A very small percentage of failures of prophylaxis may be due to a large FMH. A single dose of Ig can reasonably be expected to suppress a certain amount of hemorrhage. If the hemorrhage is large, then some amount of sensitization can take place. However, use of anti-D globulin reduces the probability of immunization and; therefore, depending on the concentration of both antibody and antigen, the actual immunization frequency can be reduced to very small numbers but never to zero.

**MONOCLONAL VERSUS POLYCLONAL**

Immune suppression by passive antibodies in general is brought about by clearance of the antigen and immune deviation, i.e. nonexposure to antibody producing tissues. Clearance of the antigen could happen in Rh(D) negative mother by intravascular lysis as it happens in ABO incompatibility or by extravascular phagocytosis. Using an in vitro model, it has been shown that although both clearance and antibody-dependent cell-mediated cytotoxicity (ADCC) take place with both monoclonal antibodies and polyclonal antibodies, the ADCC activity is better with polyclonal antibodies than with monoclonal antibodies [(BRAD-3(IgG3) or BRAD-5(IgG1)]. This is because polyclonal antibodies interact better with the Fc receptors on the splenic cells. Further trials of antenatal and postnatal prophylaxis in Rh(D) women using monoclonals BRAD3 or BRAD5 are required to prove that they are suitable for the prevention of Rh(D) HDN.24

There is a report from Russia about the creation of a human-mouse heterohybridoma producing monoclonal IgG3 (cell-line HG-48/92).25 However, this preparation contains only IgG1 anti-D antibodies and not IgG3, which are important in removal of Rh(D) antigen through monocyte-mediated ADCC activity.

It would seem prudent to use a blend including both IgG1 and IgG3 antibodies.

In most instances, the current polyclonal anti-D consists of both IgG1 and IgG3. In a study of 21 polyclonal anti-D IgG preparations, the percentage of IgG3 was found to range between 1% and 18% with a mean of 8%.26

**LABORATORY TECHNIQUES IN EVALUATING A RHESUS ALLOIMMUNIZED PREGNANCY**

**Determination of Fetomaternal Leak**

A blood sample is obtained after delivery or any other event suspected to have caused a fetomaternal bleed. This post-event sample of maternal (Rh negative) blood is then tested for quantification of fetal leak into the maternal circulation.

**Rosetting Test**

This is an initial qualitative screening test. **Principle:** Rh positive fetal cells coated with anti-D form rosettes with Rh positive indicator cells, thus, making them distinguishable from the Rh negative maternal cell population. **Disadvantage:** It is not reliable when the infant/fetus or mother is weak D (D<sup>+</sup>) positive.
Kleihauer-Betke Test

The technique first reported by Kleihauer et al.\textsuperscript{27} has been modified by Nierhaus and Betke. A thin blood smear is prepared from maternal hemoglobin (Hb). The smear is then counter stained by erythrocyn to stain fetal red cells. Under the light microscope the number of fetal cells per 100,000 maternal ghost cells are counted. The amount of fetal blood in maternal circulation is calculated with the help of a graph,\textsuperscript{28} plotted by using the data obtained by counting smears prepared by mixing known amounts of adult and cord bloods. Table 3, illustrates the relationship between the number of fetal cells and amount of blood.\textsuperscript{29}

Quantitating the volume of fetal bleed can be done by various formula, e.g.

\[
\frac{\text{No. of fetal cells } \times 5,000}{1,000 \text{ adult cells}} = \text{mL of fetal bleed}
\]

Reasons for false positive results:

- **Faulty technique:** Hb F elutes if left too long in the eluting solution
- Some fetal cells containing HbA will be missed
- Some pregnant women (10–25%) may themselves produce elevated level of Hbf between 10 weeks and 32 weeks of gestation
- Genetic hemoglobinopathies.

New tests, advocated for detecting FMH include the microscopic Du test (micro Du) enhanced with polyethylene glycol (PEGD) and flow cytometry (FC). A study comparing five methods of detecting FMH\textsuperscript{30} assessed three qualitative methods:
1. Micro Du
2. Rosette test
3. PEGD

and two quantitative methods:
1. Acid elution, i.e. Kleihauer-Betke stain
2. FC.

Of the qualitative tests, the micro Du test was the least sensitive, with 20% false negative results occurring at 0.5% fetal cells. The PEGD test was only slightly more sensitive and offered no clinical advantage. The rosette test was the most sensitive, consistently detecting fetal cells at concentrations of 0.25% or greater. FC and Kleihauer Betke test showed similar results, with good correlation between measured and expected quantities of fetal cells. Although Kleihauer Betke (acid elution) test is a more commonly used method for quantitating FMH, FC offers an acceptable alternative which is capable of analyzing large number of cells with objectivity and reproducibility.

**Prenatal Investigations**

A blood sample must be collected from every woman at her first antenatal visit, for ABO and Rh typing. This policy should be universal and carried out irrespective of the parity or what tests are performed in the previous pregnancy. Rh(D) negative women and those having partial “D” or weak “D” antigens are screened for the presence of anti-D in their serum. In-depth investigations are carried out for Rh(D) alloimmunized mothers.

**Rhesus Genotype of the Husband**

When a woman has anti-D in her serum, it is desirable to know the Rh genotype of her husband.

**Rhesus Antibody Estimation**

Rhesus antibodies are immune (IgG) in nature having the molecular weight of 160,000 Daltons. They are able to cross the placental barrier and coat fetal Rh(D) positive red cells. After the D antigenic stimulus, IgM anti-D having the molecular weight of 900,000 Daltons, appears first, which later on gets converted to IgG. Women who respond to D antigen are likely to respond to “C” or “E” antigens of the Rh system. Hence, it is essential to screen all Rh(D) alloimmunized mothers for anti-C and anti-E response also.

Rhesus antibody titer and quantitation are the tests employed for estimation of Rh antibodies, in maternal serum.

**Rhesus Titer**

Manual Rh titration is a universally accepted test because it is simple, cheap and can be easily repeated frequently. A rise in Rh titer indicates a Rh(D) positive fetus. Several techniques are available to perform this test.

- Indirect antiglobulin test (IAT)\textsuperscript{31}
- Albumin method\textsuperscript{32}
- Enzyme method\textsuperscript{32}

**Quantitation of Anti-D Concentration**

Rhesus titer, being a semi-quantitative, visual test, results may vary from person to person. Therefore, autoanalyzer methods have been developed to quantitate Anti-D in \(\mu g\) amounts.

- Bromelin method

\]
Hemoglobin and hematocrit (Hb and HCT)

The normal values in the second trimester are 14 g/dL for Hb values for Rh HDN. Generally, a strongly positive (++) reaction indicates a severely affected fetus. Liley’s method, is considered reliable only for pregnancies from 27 weeks to term. Therefore, many workers have suggested modification in the Liley’s graph to evaluate the results of the amniotic fluid collected between 14 weeks and 26 weeks of gestation. It has been observed that considerable number of optical density values fall in Zone II (beginning or middle) even when the fetus is Rh(D) negative, hence an intrauterine transfusion (IUT) is recommended only if results indicate the end of zone II or zone III. Amniocentesis is recommended approximately 10 weeks prior to the occurrence of a previous adverse event such as the delivery of a hydropic, still born or a severely anemic infant.

INVESTIGATIONS OF THE FETUS

Rhesus Typing

Prenatal DNA based Rh typing of the fetus is possible as early as the 9th week of gestation, using trophoblasts recovered from the endocervical canal. DNA obtained from fetal cells in the maternal peripheral blood or amniotic fluid could also be used to determine the Rh status by PCR amplification.

Studies describing the second trimester screening test in reproductive health negative pregnancies conclude that either the connected value should be referred or double test result should be considered ignoring the unconjugated estriol result. Another option is the first trimester, Down’s syndrome screening test.

Fetal Blood Sampling

Specific indications of fetal blood sampling in Rh alloimmunization:

- All hydropic cases
- Optical density deviate (ODD) 450 result -> high zone II on Liley’s chart
- Rapid rise in ODD 450 value
- Risk of severe anemia in early to mid second trimester
- Fetal blood typing (e.g. heterozygous father)
- Unavoidable transplacental needle passage

Fetal blood for examination is obtained by cordocentesis.

Cordocentesis or Percutaneous Umbilical Sampling (PUBS)

Daffos and associates introduced PUBS in 1983, to diagnose fetal affection. In Rh-alloimmunization, PUBS is performed for immediate confirmation of the fetal antigenic status, obviating the need for further intervention in the Rh negative fetus. A detailed ultrasound examination should be performed before PUBS for evaluation of the gestational age and placental function. Fetal blood can be obtained by puncture of the fetal heart, intrahepatic portion of the umbilical vein or by puncture of the umbilical vessel close to its placental insertion, the latter being the most common and around 1-10 mL of blood can be withdrawn for diagnostic studies. Cordocentesis has also been used for repeated blood transfusion in utero for a hydropic fetus with hemolytic disease. In most of the centers now the fetal blood sample is obtained by a direct puncture of the umbilical vein under ultrasonography guidance.

Hematological parameters studied are:

- Purity of fetal blood sample: If there is a contamination with maternal blood or amniotic fluid, then one can get erroneous results. Coulter channelizer shows separate peaks of adult and fetal RBCs based on the diameter of the cells.
- ABO and Rh typing: The standard serological technique is used to determine the blood group of the fetus.
- Direct antiglobulin test (DAT): DAT reveals the presence of IgG anti-D molecules on fetal RBCs. The strength of agglutination is directly proportional to the severity of Rh HDN. Generally, a strongly positive (++++) reaction indicates a severely affected fetus.
- Hemoglobin and hematocrit (Hb and HCT): The normal Hb values during the DAT second trimester at different gestations range from 10 g/dL to 14 g/dL. During the third trimester the range is from 14 g/dL to 15 g/dL. The HCT ranges from 35% to 40% and 40% to 47% respectively. Nicolaides et al. label it as severe Rh HDN when fetal
Hb value is more than 7 g/dL below the normal mean at the same gestation and moderate when the Hb deficit is between 2 g/dL and 7 g/dL.

- **Platelet count**: Coagulation abnormalities could be associated with severe Rh HDN. A single parameter, that could be helpful in predicting hemorrhagic disorder, is the platelet count. A platelet count below 150 × 10⁹/L is considered low and an infusion of platelet concentrate is absolutely essential if the value is below 50 × 10⁹/L.

- **Immature erythrocytes**: Counting reticulocytes, erythroblasts and normoblasts could, indirectly assess the degree of destruction of sensitized fetal red cells.

### Ultrasound

Real-time ultrasound is used to detect the progression of disease from mild to severe. The findings include hepatosplenomegaly, increase in portal venous diameter and flow velocity, fluid in serous cavities, subcutaneous edema, liquor disturbances (poly- and oligohydramnios) and placentomegaly. Attempts to characterize or identify the exact sequence of the above sequelae have been inconclusive so far.

It is also seen that there is an increased flow through the umbilical vein in anemic fetuses, probably as a compensatory mechanism to maintain the oxygen saturation in the fetus with increasing hemolysis. This increased flow causes an increase in the diameter of the umbilical vein and intrahepatic portal vein. In alloimmunized fetuses the portal venous diameter can reach a maximum of 8 mm even at 25 weeks of gestation (normal < 5 mm). ⁴⁴

The presence of fluid in the serous cavities signifies severe fetal anemia in the presence of alloimmunization. De Vore and colleagues have proposed that the first site of fluid collection is in the pericardial space. They demonstrated presence of minimal amounts of pericardial fluid using M-mode echocardiography. ⁴⁵ Abnormal pericardial fluid effusion should be diagnosed only if the thickness of the fluid is more than 2 mm.

### Color Doppler

Demonstrates increased flow in the splenic vein, its branches and portal venous branches within the liver. The increased flow through the portal vein is also reflected in the ductus venosus, which appears prominent and shows a characteristic area of turbulence on color flow mapping. **The normal ductus venosus waveform has a characteristic “M” which reflects right atrial events. In anemic fetuses, the “M” pattern is maintained but with higher velocities.** In the presence of anemia, the portal venous waveform shows a “saw-toothed” appearance. Tricuspid regurgitation can be detected by color Doppler and has been used to identify fetuses, which might not be hemodynamically stable to tolerate a bolus intravascular transfusion. ⁴⁵

### Postnatal Diagnosis

Immediately after the birth of an infant to a Rh negative mother, blood from the umbilical cord or from the infant should be examined for Rh type, Hb, and reaction of the direct Coomb’s tests. Negative infant is falsely typed as Rh positive due to the locking of antigenic sites. A false negative direct Coomb’s test, is obtained if material antibody titers are low. Other essential investigations include indices of erythropoiesis (reticulocyte count, nucleated RBCs per 100 WBC) and RBC morphology. A cord Hb less than 14 g/dL is abnormal in term neonates. Reticulocyte count in Rh disease is more than 60% and may be as high as 30–40%.

### Additional Assessment

A number of studies, which are not routinely performed, may help assess the degree of hemolysis and risk of kernicterus. They are as follows:

- Serum albumin level
- Bilirubin to albumin ratio
- Serum free bilirubin
- Bilirubin reserve binding capacity (BRBC)
- Bilirubin saturation index
- Carboxy Hb level
- Exhaled carbon monoxide level
- Erthrocyte creatinine level

Tests that may suggest HDN are:

- **Rapid fall in Hb in the absence of hemorrhage and significant blood collection.**
- **Increased erythrocyte production**: Increased reticulocytes, nucleated RBCs, erythrocyte creatinine level, and stable or falling Hb level.
- **Hemoglobinuria.**

### CLINICIAN’S APPROACH TO RHESUS ALLOIMMUNIZATION

#### Fetal Transfusions

Recognition of fetal anemia is the first step in the management of an alloimmunized patient. Whereas severe anemia can be recognized, if obvious ultrasound features described above are present, early hemolysis may not produce any significant changes which may give a false impression of fetal well-being. The timing of the first intervention will therefore vary with each patient. The management of fetal anemia requires a team approach. Facilities must be available for obtaining “O” negative packed cells with a high HCT. Some centers advocate the use of washed and irradiated packed cells. In hydropic cases, a fetal blood sampling and a transfusion are done at the same sitting. In nonhydropic cases, the transfusion may be postponed to a later date if the fetal HCT is greater than 30. ⁴⁶

Several routes have been tried to infuse packed cells into the fetus. Intraperitoneal transfusion was the earliest method
tried even before the advent of ultrasound. The ability to access the fetal circulation percutaneously under real time ultrasound guidance has led to the use of the umbilical vein or portal vein as the common site for IUT. The basic objective in IUT is to correct the anemia at the optimal time with the appropriate quantity of RBCs.

**Intraperitoneal Transfusion**

The use of intraperitoneal route is on the decline after direct access to the fetal circulation was made possible. It is effective in non-hydropic cases and is resorted to only if vascular access is not available due to fetal position or there is a need to perform a transfusion prior to 20 weeks.

**Intravascular Transfusion**

Vascular access to the fetus can be achieved through the umbilical vein near the insertion into the placenta, in the free loop of the cord or near the fetal insertion of the cord. A more recent approach is through the intrahepatic portal vein, which is an ideal site for transfusion. The volume of blood to be transfused depends on the donor HCT, fetal HCT and the fetoplacental blood volume at this period of gestation. A chart gives the approximate volume to be transfused.

**Another Guideline**

Volume of packed cells [(desired HCT – Actual HCT) × estimated fetoplacental blood volume × estimated fetal weight (kg)]/donor HCT.

The cells are transfused at the rate of 1–2 mL per minute. Constant monitoring of the fetal heart is done to look for fetal bradycardia, which if noticed is an indicator to suspend the transfusion. The volume of blood to be transfused depends on the donor HCT, fetal HCT and the fetoplacental blood volume at this period of gestation. A chart gives the approximate volume to be transfused.

**Complications**

- The most dreaded complication during transfusion in the umbilical cord is cord hematoma, which occurs if the needle slips into the Wharton’s jelly. Immediate bradycardia is noticed and can lead to fetal demise, if not recognized.
- Fetal exsanguination is rare but can occur especially in cases where there is severe thrombocytopenia.
- Chorioamnionitis is another potential complication the risk of which can be minimized by adhering to strict aseptic principles and antibiotic cover.
- Preterm labor can occur especially in fetuses with polyhydramnios. Tocolytics prior to and after the procedure minimizes the risk of preterm labor.
- Placental abruption has been reported but is a relatively rare occurrence.

**Suppression of Rhesus Immunization/Alternative Therapies**

**Plasmapheresis**

This is a cumbersome procedure, which does not obviate the need for IUTs. Soon after the plasmapheresis is stopped, the anti-D titers increase in a “rebound” phenomenon. Moreover, it reduces the maternal levels of viral and bacterial antibodies with a resultant predisposition to infection.

**Promethazine Hydrochloride**

Studies with matched controls have shown no benefits with promethazine.

**Intravenous Immunglobulins**

Thought to act by either blockade of Fc receptor in the fetal reticuloendothelial system, thereby inhibiting the removal and destruction of fetal anti-D coated erythrocytes by the fetal spleen and liver. Also thought to act by blockade of the Fc-mediated antibody placental transport, thus limiting the trans-placental passage of anti-D to the fetus. This treatment has been used by a number of authors.46,47

In a study, it was found that intravenous immunoglobulins (IVIGs) is effective in decreasing the maximum bilirubin
levels and the need for repeated exchange transfusions in reproductive health hemolytic disease of newborn. There is however, an increased need for blood transfusions for late anemia in the babies treated with IVIG.\textsuperscript{50}

**Other Treatment Modalities**

Oral desensitization with erythrocyte membrane IG therapy and transfusion of marrow stem cells from the Rh negative mother to the Rh positive fetus has been tried. Oral administration of the Rh-antigen has also been tried in an effort to suppress the secondary immune response.

**Antenatal Monitoring of Fetal Heart**

It is of value but does not help to a great extent in the management. Abnormal fetal heart rate patterns have been described in severe Rh alloimmunization. Sinusoidal and decelerative patterns have been associated with very low cord Hb concentrations at delivery\textsuperscript{51} and high perinatal deaths.\textsuperscript{52}

**Delivery of the Fetus**

The time of delivery is determined by the clinician, taking into account a number of factors which would include:

- The gestation age of the fetus
- The severity of affection
- The survival rates of the neonatal intensive care unit of the concerned center.

Each case should be carefully considered on an individual basis, before arriving at a decision.

In pregnancies where the fetus is only mildly affected, the pregnancy is allowed to continue till term, provided the fetal well-being studies so permit. Labor is induced at 36–37 weeks of gestational age. An unfavorable cervix is initially ripened with the use of prostaglandin gel. Continuous intrapartum monitoring should be utilized to detect a distressed fetus and an operative delivery resorted to whenever indicated.

When the fetus is severely affected, the fetus is delivered earlier, and the timing of delivery would be determined by the survival figures of the concerned neonatal care unit. The fetus should be delivered as early as 32–34 weeks, provided pulmonary maturity is demonstrated by a prior amniocentesis. A lecithin: sphingomyelin ratio greater than two and the presence of glycerophospholipid indicate a mature pulmonary system. If the lungs are still immature, delivery can be performed after administering corticosteroids to the mother.\textsuperscript{48,53}

In conclusion, a small well-knit team comprising of obstetricians, sonologists, blood bank personnel, neonatologists and nursing personnel working in close coordination is required for successful management of alloimmunization. Early reference with assessment and judicious intervention as well as intensive neonatal care is essential to ensure satisfactory results.

**Management of the Erythroblastic Baby After Birth**

**Management at birth:** Therapy immediately prior to delivery should include drainage of large pleural effusions and ascites to facilitate postnatal gas exchange.\textsuperscript{54}

If the infant is very ill, (premature and/or hydropic), tracheal intubation and positive pressure ventilation may be necessary. Initially, a partial exchange transfusion and later a double volume exchange using blood with a normal HCT to normalize the Hb and HCT is advocated.

**Prevention of Bilirubin Encephalopathy**

Phototherapy followed by double volume exchange transfusion in the event of phototherapy “failure” remains the mainstay of treatment for hyperbilirubinemia due to disease.

**Phototherapy**

It should be started in term neonates if bilirubin rises 0.5 mg/dL/hr or greater, or if total bilirubin exceeds 10, 12 or 14 mg/dL at less than 12, less than 18 or less than 24 hours of life respectively. It should be initiated at lower levels for premature neonates in the first 24 hours. Blue light at 450 nm appears to be the light source absorbed best by infants.\textsuperscript{55}

Special care of the infant getting phototherapy includes the use of eye patches and diapers to prevent exposure to direct light. Babies are monitored for development of hyperthermia, diarrhea, dehydration, serum calcium levels and bronze baby syndrome.

**Exchange Transfusion**

It remains a major effective means of managing hyperbilirubinemia and of ameliorating neurotoxicity in the severely affected newborn.

The objectives of exchange transfusion are:

- To remove antibody coated red cells, which are potentially lethal sources of bilirubin, and to replace them with red cells compatible with the mother
- To remove the bilirubin
- To remove the antibody that would combine with any new red cells produced by the infant.

**Other Modalities of Treatment**

**Hemoygenase inhibitors:** Inhibition of bilirubin production may be a more effective therapy in patients with Rh disease. The enzyme hemoygenase catalyses the rate limiting step in bilirubin production, the conversion of haem to biliverdin. However, there is limited success with this mode of treatment.\textsuperscript{56}

**Intravenous immunoglobulin:** It has been used in the prenatal management of Rh sensitized women, in which case the possible mechanisms of action include:

---

**SECTION**

**Fetus as a Patient**

234
• Feedback inhibition of antibody synthesis through modulation of maternal T or B lymphocytes or both
• Blockade of F-mediated antibody transport across the placenta
• Blockade of Fc receptors on macrophages in the fetal reticuloendothelial system which is the site of red cells destruction. Postnatal treatment with IVIG may block neonatal Fc receptors and hemolysis.57

Studies document the possibility that, the frequency of transfusion therapy can be reduced by combining conventional phototherapy with high dose IVIG.58 The therapy is reported to be without adverse side effects.59

**Phenobarbital:** Prenatal and postnatal phenobarbital therapy has received considerable attention in the treatment of Rh disease, particularly in the era before improved phototherapy. It accelerates bilirubin clearance by increasing its uptake by the liver, increasing its conjugation by uridine diphosphate glucuronyl transferase, and increasing the excretion of conjugated bilirubin by increasing bile flow. Further studies and documentation of its safety are needed before phenobarbital therapy can be considered for routine use.

**Clofibrate:** In France, clofibrate, an inducer of glucuronyl transferase activity and of the two transport proteins, is reportedly more efficient than phenobarbital therapy.

### RHESUS ALLOIMMUNIZATION: THE FUTURE

Awareness needs to be created among medical staff and relevant health authorities. Educational information or information leaflets about the guidelines to prevent alloimmunization could be given to Rh(D)-negative women and their partners and relevant health professionals. Routine antenatal prophylaxis in all Rh(D)-negative women has the potential over time, to save more resources than if restricted only to primigravidae.

Attempts are on, to try various other methods of prevention of Rh alloimmunization. One of them is the use of Rh(D) antigen coated enteric tablets, as a desensitization procedure.60 Till the time, an effective method is found the use of Rh(D) IG in Rh(D)-negative mothers is the only effective solution for eradication of Rh alloimmunization.

### CONCLUSION

The conquest of Rh disease by a two-pronged approach has paid rich dividends. Administration of anti-D to Rh-negative mothers has greatly reduced the number of sensitized pregnancies. Combined with this, effective in utero treatment has helped to salvage about 80–85% of affected fetuses. However, in developing countries, the problem will persist due to various reasons like nonavailability of anti-D in remote areas and unaffordable cost for the lower socioeconomic group of patients.

Fetal Surveillance: Newer Developments

INTRODUCTION

During the last 30 years, antepartum fetal surveillance has evolved into complex methods of fetal testing the earliest and most widely used being electronic fetal heart rate (FHR) monitoring, e.g. contraction stress test (CST) and nonstress test (NST). Both of these tests are reliable indicators of fetal well-being with false negative rates of less than 1/1,000. NST is the most widely used primary test of antepartum fetal testing (AFT). With advent of real time ultrasound, biophysical profile (BPP) and amniotic fluid volume/index (AFV/AFI) were developed to reduce false positive rates of NST, estimated to be as high as 65% and to prevent unnecessary obstetrical interventions. Primary goals of any fetal testing program must be to prevent fetal demise or asphyxia and resulting long-term neurologic sequelae, and to guide further intervention of either pregnancy termination or continuation with reliable predictability of fetal health or compromise. With universal use of AFT in management of high-risk pregnancies, fetal deaths in United States of America have reduced from 18/1,000 in the 1950s to 7.5/1,000 in the 1990s. Validity of AFT in reduction of fetal deaths is demonstrated in Table 1. Fifty percent of fetal deaths appear to be preventable and occur predictably in maternal fetal conditions listed in Table 2.

Many newer concepts of AFT, e.g. condition specific testing, automated methods of assessment of NST, modified BPP using NST and AFV, individualization of activities during BPP, intrafetal cardiac and vascular flow measurements, etc. are available today to improve predictability of fetal health or compromise.

| Table 1: Validity of antepartum testing |
|-------------------------------|------------------|
| Condition                        | Death/1,000 births |
| Previous stillbirth              | 30 | 6.1 |
| Insulin-dependent diabetes mellitus (IDDM) | 50 | 16 |
| Hypertension                     | 26 | 7 |
| Untested                         | 10.8 | 53,027 |
| Tested                           | 0.8 | 15,842 |

NONSTRESS TEST

Nonstress test utilizes FHR accelerations in association with movements to be a sign of fetal well-being, indicating
integrity of fetal peripheral receptors, spinal cord, autonomic nervous system and myocardium. Beat to beat variability of FHR is produced as a result of balance between sympathetic and parasympathetic components of the autonomic system. A reactive NST is defined as presence of at least two FHR accelerations of 15 bpm lasting 15 seconds within a 20 minutes period in association with movements. The diagnostic value of NST is as reliable as its predecessor, CST; however, its false positivity remains up to 65–70%. A cumulative review of 50,000 cases revealed a perinatal mortality (PNM) of 6.2/1,000. Wide variations in false positives of NST are observed by many investigators, however, false negative rates remain low indicating it to be good predictor of fetal well-being (Table 1). AFT is indicated in maternal fetal conditions where fetal deaths are threatened (Table 1). Optimally fetal testing should begin at gestational age of 32 weeks in absence of severe complications in most high risk conditions. However, testing anytime after the viability age of 26 weeks in complicated diabetes, hypertension or severe intrauterine growth restriction (IUGR), etc. may be warranted. Most perinatal centers choose to perform NST twice weekly to ensure a lower false positive rate of 0.8/1,000 versus 1.9/1,000 when NST is done weekly.

**Diabetes**

Poorly controlled diabetic pregnancy is at risk for fetal demise as a result of vasoconstriction associated with hyperglycemia. Additionally, large infant of a diabetic mother is more prone to hypoxia. AFT reduces the risk of fetal loss from 50/1,000 to 16/1,000 deliveries. Twice weekly testing is currently the norm in most perinatal centers. Some have advocated routine weekly BPP. Data presented here under fetal acid-base balance section does not support such an approach. NST appears to be the most sensitive detector of fetal acidemia. Minor variations in either FHR pattern or breathing does not appear to always indicate fetal acidosis, conversely acidotic fetuses will generally exhibit a nonreactive NST and/or late decelerations.

**Multiple Gestations**

Perinatal mortality in twins is known to be higher as a result of twin-twin transfusion, discordant growth, or IUGR of one or both twins and hence AFT is essential to allow for timely intervention to prevent death. A reactive NST appears to be of similar value in prediction of fetal well-being as in singletons. Knuppel demonstrated that late fetal deaths can be eliminated by routine testing of twins from 32 weeks. Blake et al. tested 94 pregnancies. Eighty-nine percent of reactive fetuses had uncomplicated outcomes while nonreactive fetuses had a sixfold PNM than reactive fetuses (12/1,000 versus 80/1,000). Simultaneous testing of both fetuses allows each twin to act as a control for its cotwin. Longitudinal studies of simultaneous NSTs in twins reveal synchronous accelerations of FHR to be more frequent in early third trimester and decrease to 46% at term. This synchronicity appears to be a proprioceptively originated by one or the other twin. Testing of twins poses a dilemma of management when a combination of reactive and nonreactive NSTs are encountered, particularly in a pregnancy remote from term. Age-related compromise of a normal twin has to be factored into the management schema.

**Post-term Pregnancy**

Testing for a postdate fetus should ideally begin at 41 weeks in well-dated patients. Special consideration must be given to accompanying amniotic fluid content. A general approach to delivery of all at 42 weeks can be justified to prevent compromise of 10–20% of fetuses. Miyazaki and Miyazaki have shown variable decelerations to be of particularly adverse significance in postdate fetuses mandating delivery.
Placental Insufficiency
Cases of hypertension, renal disease, IUGR or any other conditions exposing the fetus to hypoxic compromise should be tested at appropriate time and frequency. FHR amplitude, strength and frequency of movements decrease in IUGR babies. Amniotic fluid assessment by AFV or AFI remains of special significance as an important function of placental perfusion for these babies.

AMNIOTIC FLUID VOLUME/INDEX
It is recently recognized that AFV is an important component of fetal evaluation by virtue of it being the only indicator of placental perfusion and fetal urine output within any testing scheme of AFT, e.g. BPP. A threshold of a single maximum vertical pocket of greater than 1 cm of AFV (MVP) was considered reassuring within the original BPP described by Manning in 1980. Chamberlain et al. demonstrated that a single largest vertical fluid pocket (MVP) of 2–8 cm was the norm in third trimester and MVP of 1–2 cm was considered marginal. PNM with normal, marginal and decreased MVP was 4.5/1,000, 56.6/1,000, and 187.5/1,000 respectively. Phelan developed the concept of an AFV, a four quadrant quantitative measurement of largest vertical pockets. In a later study, a value of 8–18 cm was considered to be normal and less than 5 cm was associated with increased PNM in the third trimester. AFV may now be used as an alternate to the MVP in the schema of BPP as a measure of fluid content in utero. An only available study comparing AFV and maximum single pocket technique by Fisher found a 2 cm pocket to be of reassuring value similar to the AFI.

The chances for development of oligohydramnios within 4 days were 1/200 with a normal AFI of 8–18 cm and 5/100 for a marginal AFI of 5–8 cm. Hence, it is prudent to test a fetus for oligohydramnios every 4 days whereas an interval of 7 days appears sufficient in normal cases.

Biophysical Profile
Advent of real time ultrasound has heralded our sense of fetus as an individual having not only heart rate, but displaying physiologic behavior pattern. Biophysical profile (BPP), first described by Manning, uses reactivity of FHR at NST, fetal breathing movements (FBM), fetal movements (FM), fetal tone (FT) and AFV, the last four observed ultrasonically (Table 4). Presence of each factor is assigned a score of 2, 10 being a perfect score assuring fetal well-being and a score of 0 is indicative of severe fetal compromise threatening demise. Manning then demonstrated an increasing PNM, fetal acidemia and cerebral palsy with decreasing BPP score.

Biophysical Profile and Perinatal Mortality and Morbidity
Biophysical profile was first reported on by Manning et al. in 1980 using all five parameters of fetal activity individually and then in combination in 216 patients. The corrected PNM was 32.4/1,000. The positive prediction was highest with absent FBM and lowest with a nonreactive NST and the false negative was lowest with absence of FT and highest with a nonreactive NST. FBM appeared to be the most complex and sensitive function of well-being and FT was the least sensitive. The activities and their presence or absence reflect developmental order and the complexity of the neural center governing each activity. The most evolved centers lose function earlier with the advent of fetal hypoxia-acidemia.

Manning and coworkers used BPP in clinical management of 12,620 pregnancies, and reported a corrected PNM of 1.9/1,000 and a false positive rate of 0.6/1,000 within a week following a normal BPP. Corrected PNM has shown to vary between 0 and 26/1,000 in several other studies using BPP in a schema of AFT. Thereafter, PNM was reported to be reduced by 76% in Manitoba in 55,551 tested patients compared to 104,337 nontested fetuses. Similar reduction in immediate morbidity, e.g. operative delivery for fetal indications, intrapartum fetal distress, low Apgars and birth weight, and NICU admissions were observed in association with a normal BPP.

BPP and Acidemia
A significant inverse relationship exists between BPP and umbilical pH. A normal BPP of greater than 8/10 has not yet been found to associate with a fetal pH of less than 7.23 by cordocentesis. In a review of multiple studies including 572 patients, 14% cases had low BPP less than 6. Abnormal pH occurred in 48.19% in those with low BPP and in none with a normal BPP score of greater than 8/10. Manning correlated fetal acidosis with BPP and concluded that at a BPP of 4/10 or less:

- Fetal compensation ability is reduced, and metabolic acidosis begins. The risk of significant acidosis (pH < 2.0)

</table>
Manning reported 83% for NST, 22% for normal AFV, 13.6% for abnormal AFV, 2% for nil AFV, and 9.6% for AFT. A combination of a reactive NST and normal AFV rules out acidemia and no further testing need be done (modified BPP).

- Oligohydramnios is independently associated with acidemia.
- Acidemia is present when all activity parameters of BPP are abnormal regardless of AFV.
- BPP acute markers reflect fetal acid-status at the time.
- Loss of NST and FB are the earliest markers of compromise and loss of FM and FT indicate advanced stage acidemia.

Using a modified BPP program of testing with NST and AFI, in 17,211 cases, four fetal deaths were observed, with a false negative rate of only 0.02%.33 The incidence of CP rose sharply at BPP score of 2/10 or less.

### BPP and Cerebral Palsy

Cerebral palsy (CP), a neurologic disease involving muscular function occurs as a result of perinatal insult during the antepartum, intrapartum or neonatal periods. BPP contributes to prediction of CP by excluding or including the risk of fetal asphyxia during the antepartum period. When BPP results were used to guide intervention, 26,288 tested fetuses had a CP rate of 1.33/1,000 versus 4.72/1,000 untested fetuses.33 The need for NST was reduced to 5% of all patients during ultrasound.

The incidence of CP rose sharply at BPP score of 2/10 or less.

### Modified Methods of Biophysical Scoring

1. **Use of ultrasonic components only:** Manning reported similar benefits in reduction of PNM as with classic BPP. The need for NST was reduced to 5% of all patients requiring caregivers to perform ultrasonic testing only. Diagnosis of fetal anomalies was an additional benefit during ultrasound.

2. **Use of AFI to substitute for the largest vertical pocket measurement of AFV.** No significant differences in outcome are seen with both methods of AFV assessment. However with advent of the test described below, use of AFI can be justified as a routine test.

3. **Modified BPP using NST/AFI testing:** A reactive NST denotes FHR reactivity in association with FM abilities. Addition of AFI tests three of the five features of the classical BPP. NST and AFI, used in combination as a modified BPP test, appear to be physiologically sufficient as an AFT. Nagoatte34 showed a fetal death rate of 1 in 18,947 patients with a false positive rate of 0.05%. Vintzileos35 found a similar correlation with NST and AFV in the schema of management of 17,211 patients. Both of the above researchers correlated normal tests with normal fetal acid-base status with a false negative rate of 0.02%. In many perinatal centers in United States of America modified BPP is widely used now as a primary modality of AFT. It appears to be a reliable modality of primary AFT as a full BPP, reserving BPP and CST to a second line testing scheme for special cases.

### UMBILICAL ARTERY DOPPLER VELOCIMETRY IN ANTEPARTUM FETAL SURVEILLANCE35

Doppler flow assessment in the fetoplacental and intrafetal circulation is increasingly gaining importance in a comprehensive program of fetal surveillance to gain knowledge of fetal hemodynamics. Hemodynamic compromise is often at the root of abnormal fetal function assessed by surveillance measures described above. Umbilical arterial Doppler (UA) waveform is biphasic. A systolic component reflects forward flow while the diastolic component represents vascular resistance in the placental bed. Systolic/Diastolic velocity ratio (UA S/D) progressively declines with pregnancy due to decreasing resistance in the placental bed with advancing gestational age. It is less than 3 by 30 weeks of age when vasodilatory process in the placental villi is optimized. Absent diastolic flow (ADF) or worse, reverse diastolic flow (RDF) indicate severe resistance in the fetoplacental circulation and are often associated with fetal growth abnormalities, hypoxia-hypercarbia and acidosis.

Greater than 70% of placental obliteration is needed to result in ADF or RDF patterns (Table 5, Serra-Serra).36 Divon37 reported a meta-analysis which included 6,838 patients, showing impact of UA Doppler in clinical management to reduce PNM by 66%.

Compensatory redistribution of blood by way of vasodilatation favoring cerebral circulation can be represented by middle cerebral arteries (MCA). MCA can be easily accessed and sampled through a transverse scan of the fetal vertex depicting the circle of Willis. MCA is prominently displayed by color Doppler as biphasic wave commonly measured as pulsatility index (PI) or resistance index (RI) to predict hypoxia. UA to MCA RI less than unity may be indicative of neonatal morbidity Arias.38 In a study of blood gases by cordocentesis in 23 IUGR fetuses Hecher39 reported low resistance MCA Doppler to be associated with low pO2 and pH.

Source: Serra-Serra et al.36 1994
Venous Doppler pulsatility described later in this book occurred with further decrease in $P_O_2$ and $pH$.

Middle cerebral arteries maximum peak velocity is also used to predict anemia in cases of blood group incompatibility and other conditions (Mari). Blood flow patterns in the venous system, e.g. inferior vena cava (IVC) and ductus venosus (DV) [ductal flow is sampled in a transverse section of upper fetal abdomen at the level of its origin from the umbilical vein (UV)], reflect pressure gradient between right atrium and right ventricle indicating ventricular compliance. A marked increase in normally present small negative waveforms in the IVC and DV indicate reversal of flow and congestion in the venous system due to cardiac dysfunction and cardiac failure. Finally, appearance of pulsations in the normal monophasic waveform pattern of UV Doppler is the very last phase in deterioration of fetal hemodynamics prior to death.

In a program of fetal surveillance a stage of hypoxia progressing to acidosis is associated with occurrence of hypoxic ischemic encephalopathy (HIE) and resulting long-term sequelae of neurologic deficit in the infant or even fetal demise. Hence, it can be assumed that majority of these events can be preventable, by intensive scrutiny of hemodynamics in the fetus by peripheral vascular surveillance in the arterial as well as venous system if necessary and timely delivery prior to extreme fetal state.

Additionally, hypoxia may independently impair myocardial contractility. Despite both ventricles being exposed to different after loads, myocardial contractility is maintained until late stage hence cardiac function is seen to play an important role in IUGR fetal circulation. Cardiac failure may finally occur as direct hypoxic myocardial depression sets in.

CONCEPT OF A COMBINED TESTING PLAN

It has been suggested to use multiple parameters of AFT for best prediction of fetal state. BPP, modified BPP, etc. have been previously discussed in this report (Table 6).

Some have suggested using NST, AFV and umbilical Doppler velocimetry in combination with ultrasonic biometry for best prediction of overall fetal status. Devoe examined the reliability of NST, AFV and UAV in 100 high risk patients. AFV and UAV were less powerful than NST in prediction of fetal status.

In a study of multiple fetuses, Gandhi found UAV to be extremely useful in prediction of IUGR and discordant growth in 52 pairs of twins. IUGR could be predicted 80% of the time in combination with biometry compared to 45% of the time with biometry alone. Further, abnormal UAV was observed two weeks in advance of the biometric abnormality indicating IUGR.

- Newest developments in fetal surveillance
- Future of antenatal testing
- Automated methods of fetal development.

Meta-analysis of fetal testing has revealed many errors current system of perinatal practice. They range from unavailability of patient data, poor documentation, equipment and record abnormalities and individual physician bias in management without the benefit of evidence based schemes of practice. Automation, computer-based data availability, analytic algorithms, or dedicated software may improve outcome. Automated perinatal intelligent program combines computerized analysis of raw fetal signals, weighs them in context of the pregnancy, assesses fetal condition, renders probabilistic prognosis and advises safest management options to the clinician. Many such programs are available most in their early or research based phases. Some, e.g. Oxford Sonicaid System 8,000 from United Kingdom is available commercially and has been used at the Medical College of Georgia for FHR analysis. Fetal BPP can be automated. The system combines an electronic FHR monitor, a real time ultrasound scanner and a computer to collect online fetal FBM, FM, FHR, etc. data, analyzing it, and ultimately rendering management options to the clinician. Artificial neural network is an essential component of any system to be clinically useful. Devoe has used such system extensively. The advantages appear to be of accuracy, precision and ability to practice evidence-based medicine.

In conclusion, AFT saves lives and newer techniques and concepts continue to improve outcome in sicker and younger babies on an ongoing basis.

INTRODUCTION
Cardiac anomalies are most common anomalies (1/3rd) found at birth. Its prevalence is 5 in 1,000 livebirths. Fifteen percent of neonatal deaths and 50% of infant deaths due to malformations are due to cardiac anomalies. Incidence of aneuploidy is 15–38% in fetuses with cardiac malformations and in livebirths. Also the incidence of aneuploidy is 11.8% in babies with congenital heart defects. Congenital cardiac diseases thus is taking a larger toll of the new born population than even the chromosomal anomalies. Therefore, diagnosis of cardiac diseases must not be missed in antenatal period. More so because many of these have good prognosis, if they are detected antenatally and can be treated immediately after birth, screening for cardiac diseases by fetal echocardiography must be included at least in the second trimester scan. Advancing technology and transvaginal approach now also allows fetal echocardiography with nuchal scan.

RISK FACTORS FOR CARDIAC ANOMALIES

Family History of Cardiac Disease (Holt-Oram Syndrome)
Mother having congenital heart disease (CHD), risk to fetus of CHD is 5–10%, though in fetuses who have fathers with CHD, the risk is lesser. Certain defects have higher (10–15%) recurrence rate, e.g. hypoplastic left heart, aortic stenosis, coarctation of aorta, 2–5% for septal and conotruncal anomalies and less than 5% for transposition of the great arteries (TGA) and single ventricle like abnormalities.

Maternal Diseases
- *Diabetes mellitus* [5% risk of CHD in fetus Ventricular septal defect (VSD), TGA, coarctation and conotruncal abnormalities]. phenyl ketonuria (VSD, coarctation of aorta, hypoplastic left heart and tetralogy of Fallot)
- Collagen disease (anti-Sjögren syndrome A or B antibodies) associated with myocarditis and heart blocks.

Teratogens: Drugs and Infections
- *Alcohol*: Patent ductus arteriosus (PDA) and septal defects: up to 25% risk of CHD,
- *Retinoic acid*: Conotruncal and great artery anomalies.
- *Anticonvulsants*: Valproic acid, phenytoin and trimethadione: PDA, Aortic stenosis, tetralogy of Fallot, TGA and coarctation of aorta
- *Lithium*: Ebstein’s anomaly
- *Daunorubicin*: Myocardial necrosis
- *Rubella*: PDA, Pulmonary stenosis, septal defects
- *Parvovirus*: Damage to myocardial cell itself.

Chromosomal Anomalies
Extracardiac anomalies are present in 25–45% of fetuses with CHD and so whenever an abnormality is found any where in the body, the heart must be evaluated with care.

Monozygotic Twins
Monozygotic twins have double incidence of CHD and risk is much higher in conjoined twins.

Arrhythmias
Septal defects.
Nonimmune Hydrops

The last two actually indicate that there is a possibility of CHD. But it is important to know that as for trisomy 21, only 30% of cardiac anomalies are detected in high-risk group, whereas 70% are detected in the low-risk group. Therefore, screening for cardiac anomalies must be included for each fetus.

Till now, by screening we meant looking at the four chambers of the heart and taking an M-mode to look for arrhythmias. But four chamber view diagnoses only 50–60% of cardiac anomalies and including outflow tracts will diagnose up to 75% of cardiac anomalies, if examined by trained experienced person.5

Approximately, 25% are still missed. A detailed fetal echocardiography is therefore essential. This must include gray scale, color Doppler, pulse Doppler and M-mode assessment all together.

**EQUIPMENT SETTINGS**

High resolution linear array, curved array or sector scanners can be used for this examination. 4–8 MHz is the preferred frequency range for this examination.

The setting for 2D imaging/gray scale is set at high contrast. The angle of the scanning field should be wide enough to include the transverse section of the thorax. The focal depth is kept sufficient so the area of interest is seen in the center of the screen, and the focal point is adjusted at the level of the heart. Orient region of interest (ROI) collinear to beam. Select smallest possible angle of insonation. Zoom the image so that the heart is seen large enough to identify all the structures but not too large that the sharpness of the image is lost. Maternal abdominal fat or scars, anterior fetal spine or limbs may make the visualization of fetal heart difficult. Using speckled reduction imaging (SRI) and compound resolution imaging (CRI) increases the sharpness of the image.

As heart has an anatomy to study and also the blood flows are to be understood, thus cardiac examination cannot be complete without color Doppler. For color Doppler high wall filter, high pulse repetition frequency (PRF), zero persistence and low color sensitivity settings are done. The color box should be big enough only to include the heart. The gains and PRF are so set that chambers of the heart are adequately filled with color but there is no aliasing. The color balance is adjusted so that both the gray scale and color can be defined adequately at a time. Using B-mode and color dual display can be helpful to correlate the anatomy and the blood flows better.

Using Zoom and Cine loop examination can be very helpful with both gray scale and color Doppler.

For pulse Doppler select small spectral sample volume to include the area of interest only with angle not more than 60°. PRF and wall filters should be high as for color Doppler. Sweep speed is set high. Remember angle corrections are required only for absolute values and not for study of waveform pattern or ratios. Spectral sample volume is placed just downstream of valve to study the flow through the valve. It is placed upstream to demonstrate regurgitation in outflow tracts. For tricuspid regurgitation (TR) the sample volume is placed across the valve. It may be placed by the help of color Doppler.

**M-MODE STUDY**

Fetal echocardiography cannot be considered complete without M-mode evaluation. The M-mode cursor is aligned perpendicular to the interventricular septum at the level of atrioventricular (AV) valves (Figs 1A and B).

Interpreting M-mode correctly is based on identifying and correlating each line of M-mode with the anatomical structure on gray scale. Ventricular chamber size is measured at the end diastole when ventricular size is the largest. Outer biventricular diameter is measured and right and left ventricular inner diameter is measured. Ventricular wall thickness and thickness of the interventricular septum are...
measured. Ventricular contractility is measured by measuring the systolic and diastolic outer dimensions and then subtracting systolic from diastolic measurement and then dividing it with diastolic measurement. Rhythm disturbances are assessed by correlating ventricular and atrial cycles when cursor passes through one atrium and one ventricle at 30° to the interventricular septum on four chamber view. M-mode can also be used with color Doppler to understand the regurge better.

B-mode scanning is the most important and color should be employed only after B-mode diagnosis for demonstration and confirmation of a particular pathology. Color may be required sometimes for identification of anatomy only when evaluation of the heart is done at 11–14 weeks scan. Though with high resolution probes and improving technology, early fetal echocardiography can be done at 11–14 weeks with the nuchal scan with transvaginal probe with 6–9 MHz frequency range.

Cardiac evaluations have been made less time consuming and much easier with advancing technology. New 4D US technology with spatio-temporal imaging correlation (STIC) (Figs 2A to C) can be used for offline 4D cardiac evaluation. After optimizing the 2D image a single sweep is taken from the upper abdomen to the upper chest in 7.5–15 seconds. Multiple images of the heart during different phases of cardiac cycle are captured and stored as a volume. This can be seen in all three planes: X, Y, Z (sagittal, axial and coronal) and can be run as a continuous cardiac cycle.

Walking through these sections give all the planes required for complete cardiac evaluation. The image can also be seen as live 3D by various rendering modes. Inversion mode of rendering can be an excellent tool to demonstrate septal defects and outflow tracts and great vessels. This mode shows all cavities as solid structures. Rendering from different angles can give all those views of the heart, which were never possible by any other modalities, e.g. basic view of the heart, which shows relationship of all the four valves, which is very informative of outflow tract relationship, inflow tract abnormalities and important for surgeons. Using tomographic ultrasound (US) imaging may also help looking at the heart at different angles. Though standardization of stored images is necessary to understand and correctly interpret them.

The new GE machines (Voluson E8) have now come up with a still easier and more standardized techniques of storage and evaluation. This software is known VCAD. When working with this, the essential views of the heart are only a finger-touch away. No manual rotations or walking through are also necessary. This makes cardiac evaluation much quicker both online and offline. However, detailed study of these techniques are out of scope of this chapter.

**EVALUATION OF THE HEART**

- As a thoracic organ
  - Situs
  - Position
  - Axis
  - Size
    - Transverse diameter
    - Cardiothoracic ratio
  - Rate and rhythm
- Internal anatomy.

**Deciding the Cardiac Situs**

Situs indicates sidedness of the heart in the chest, or may be defined on which side the apex points. Do not depend on the stomach shadow to decide the situs.

- First identify the position of the fetus: Vertex or breech and the position of the spine. Depending on this decide the left side of the fetus. If imagining is difficult in the beginning one can use a doll model for the same. Once the left side of the fetus is decided, confirm the presence of heart and the stomach shadow on left side.

- Another method, which is practically easier, is to see the fetus in its long axis on the screen and set the image so that the fetal head is seen to your right side on the screen. Turn the probe anticlockwise by 90°. Consider transverse section of the thorax as a clock face and spine is at 12 O’clock and fetal left side is at 3 O’clock. Confirm stomach in abdominal section and heart in thoracic section on left side.

Situs solitus which is a normal situs means that stomach is on left side and heart on left with morphological right atrium (RA) on right side and morphological left atrium (LA) on left side. The apex of the heart points towards left and that is levocardia (Figs 3A and B).
Abnormal Cardiac Situs

- **Solitary dextrocardia:** With normal position of all other viscera, the heart is on right side (apex of the heart points towards right side).
- **Situs inversus:** All the viscera and the heart are on the opposite side like a mirror image.
- **Situs ambiguous:** Undetermined visceral situs, position of the stomach may be right or left, polysplenia (bilateral left) or asplenia (bilateral right), may be seen.

Situs abnormalities are commonly associated with structural cardiac anomalies (Table 1).

Cardiac Position

Lines intersecting at point P showing cardiac position (Fig. 4). This means actual location of the heart in the chest is decided by point P. This point is where interatrial septum touches the posterior wall of atria. Point P is almost at the center of the transverse section of the thorax. That means normally two-thirds in left and one-third in right chest. Any intrathoracic lesion, diaphragmatic hernia, lung hypoplasia etc. will lead to abnormal cardiac position. A heart which is displaced towards right side is still a levocardia, if the apex points towards left (Fig. 5) and a dextrocardia if the apex points towards right.

Cardiac Axis

Draw one line passing through the interventricular septum on four chamber view of the heart and a second line passing from sternum to spine. The angle formed anteriorly between the two lines is cardiac axis. It is normally 25°-65°. 79.3% of fetuses with cardiac/intrathoracic defects had abnormal cardiac axis (Fig. 6).

According to Crane et al. when axis is more than 65° outflow tract abnormalities are more likely and when it is less than 25° inflow tract abnormalities are more likely.

Cardiac Size

Transverse diameter of the heart (Fig. 7) in mm on four chamber view is less than number of weeks of gestation, after 22 weeks. If this is more, cardiac area to thoracic area ratio is taken and up to 30% is considered as normal. Enlargement suggests failing heart.
Rate and Rhythm

Normally at 5th week, cardiac activity is slow like peristalsis with a rate of 60–80 beats/minute, at the end of 5th week it reaches 100 beats/minute, at the end of 6th week it is 105–130 beats/minute and at 9 weeks it is 160–170 beat/minute, and then settles down at 120–160 beats/minute. It is called bradycardia when the rate is less than 100 beats/minute, and most likely it is due to heart blocks. Fifty percent of fetuses with bradycardia have structural cardiac defects like AV septal defects, ventricular inversion, Heterotaxy syndromes and corrected TGA.

It is tachycardia, if heart rate is more than 200 beats/minute. Atrial or ventricular arrhythmias may lead to cardiac failure and hydrops.

STUDY OF INTERNAL CARDIAC ANATOMY

The heart has four chambers, two septae, two AV valves and two outflow tract valves and inflow tracts into atria. Systematic study requires several views, which would show anatomy and circulation of all these structures (Fig. 8).

These are as follows:
- Four chamber view
- Left ventricular outflow tract (LVOT)
- Right ventricular outflow tract (RVOT)
- Three vessel view
- Short axis view
- Arch views.

A transverse section of the thorax at the level of fourth rib, gives a four chamber view (Fig. 9). This can be done by...
rotating the probe transverse after seeing the thoracic spine or by moving the probe cephalad from the transverse section of the abdomen, which shows a stomach bubble. A correct four chamber view will have only one rib in the transverse section of the heart. If one can see multiple rib ends it means it is an oblique section and will give erroneous calculation of cardiac size and axis and also erroneous impression about the symmetry of the cardiac chambers. All the other views can be achieved by systematic rotational or sliding movement of the probe from this view.

After several trials by several people, these movements of the probe have been systematized.

- **Cephalad sweep**: When fetus is supine or left side of the fetus is near the transducer.
- **Rotation towards left shoulder**: When interventricular septum is transverse or tangential.
- **Five short axis views** by Yagel et al.

### Cephalad Sweep

Using four chamber view as reference point the US beam is directed—angulated cephalad in a transverse plane till the neck is imaged and includes five imaging planes.8

**Level 1**: Four chamber view.

**Level 2**: LVOT—ascending aorta.

**Level 3**: RVOT—pulmonary trunk with its bifurcation running perpendicular to ascending aorta.

**Level 4**: Ductus arteriosus originating from the pulmonary trunk bifurcation runs directly posterior and to the left of the spine to join the aorta on rotating the probe to 90°.

**Level 5**: Transverse aortic arch: going from right side of the chest to descending aorta. Rotating the probe to 90° at this level shows aortic arch with neck vessels.

### Rotational Sweep

This has two variations:

1. **When interventricular septum is perpendicular to the beam**: From four chamber view rotate transducer 45° towards left shoulder of the fetus, so that beam bisects a plane between the left hip and right shoulder of the fetus. This shows LVOT—aorta and its curve as transverse part of the arch. Rocking the probe cephalad from this position shows RVOT—pulmonary trunk coursing perpendicular to the aorta.

2. **When interventricular septum is tangential to the US beam**: the angle of rotation increases or decreases depending on the angle of the interventricular septum, before the cephalad angulation.

### Five Short Axis Views

These were first described by Yagel et al. and have been claimed to be simpler in few fetal positions.10 First upper abdominal section is taken through stomach, second traditional four chamber, third five chamber, when aorta root is seen in the center of the four chamber view of the heart, fourth transverse view showing bifurcation of pulmonary trunk with aorta in the center which confirms the crossing over of great vessels, as aorta is seen in short axis and pulmonary trunk in long axis (Figs 10 to 15) and fifth showing three vessels and trachea.

We have seen that for any heart position four chamber view is the baseline and only four chamber view diagnoses 50–60% of cardiac anomalies. So, we shall first discuss four chamber view in detail and then the outflow tracts, short axis views and arch views.

Now let us understand what all the different views show.
FOUR CHAMBER VIEW

As name suggests it shows all four chambers of the heart in its long axis. This may be apical, basal, lateral/oblique. The view is apical when the apex is towards the probe, basal when base of the heart is close to the probe, lateral when interventricular septum is perpendicular to the probe and tangential when interventricular septum forms an angle with the US beam. Structures to be identified on four chamber view:

- Cardiac size and axis
- Two ventricles
- Two atria
- Atrial and ventricular septae
- Atrioventricular valves
- Pulmonary veins draining to LA
- Atrioventricular concordance.

On this view the chamber closest to the spine should be the LA and the one closest to the anterior thoracic wall is right ventricle (RV). Left ventricle forms the left heart border.

Features of Normal Four Chambers

- Cardiac area is approximately 1/3rd of thoracic area
- Cardiac axis 25°–65°.
- Both ventricles approximately same in size, ratio 1: 1.1 to 1: 1: 2. Morphological RV is identified by thicker walls due to...
to chordae tendineae/moderator band and is close to the anterior thoracic wall.

- Both atria approximately same in size. Morphological LA is the one in which the flap of foramen ovale opens and is the chamber closest to the spine. RA may show Eustachian valve lateral to foramen ovale and must not be mistaken for a mass.

Asymmetry is seen in almost all cardiac defects except
- Tetralogy of Fallot
- Double outlet RV
- Transposition of the great arteries

- **Interventricular septum:** Shows foramen ovale in its mid part, the flap of which opens into morphological LA. The upper and lower third of the atrial septum is always seen as a thin line from posterior atrial wall and from the crux of the heart respectively. Normal diameter of foramen ovale is 75–100% of the aortic root diameter. On color Doppler it shows a peak systolic velocity (PSV) of 45 cm/sec and flow seen from RA to LA.

- **Interventricular septum:** It has three parts but only the muscular part is seen on four chamber view. Subpulmonary part is evaluated on short axis view and perimembranous part on long axis view. Interventricular septum is best seen when it is perpendicular or tangential to the US beam that is in lateral or oblique four chamber view. The septum must be seen in its full width from side to side by sweeping the beam to stamp it as normal.

- **Atrioventricular valves:** Mitral valve = 1:1.1 to 1:1.2. Tricuspid valve is attached slightly more towards the apex than mitral at the intravenous (IV) septum and the attachment of the septal cusps of both the valves with the septum makes a cross which is known as crux of the heart. Color and Doppler to detect stenosis or regurgite.

- **Pulmonary venous (PV) drainage:** At least two pulmonary veins should be seen entering the LA, which rules out total anomalous PV drainage.

- **Atrioventricular concordance:** Concordance means the morphological RV is connected to the morphological RA with the tricuspid AV valve and vice-versa for left side.

**Four Chamber Alone can Tell us About**

- Ventricular hypoplasias
- Inflow or outflow tract anomalies due to chamber asymmetry
- Atrioventricular valvular abnormalities
- Septal defects
- Myocardopathies—thickened walls and decreased contractility
- Arrhythmias—by visual impression though confirmation is always by M-mode.

Apical or basal four chamber view are good for inflow tracts and lateral four chamber view is required for evaluation of septae.

---

**LEFT VENTRICULAR OUTFLOW TRACT**

Figure 10 demonstrates the ascending aorta coming out of the left ventricle running anteriorly and to right from the ventricle. The crux seen on four chamber view is obliterated in this section and instead two parallel lines, which is the aorta. The posterior wall of the aorta shows continuity with the anterior leaflet of mitral valve and superior wall is contiguous with interventricular septum. This is the membranous part of the interventricular septum and VSDs of tetralogy of Fallot can be seen on this section.

**RIGHT VENTRICULAR OUTFLOW TRACT**

Figure 11 shows pulmonary trunk coming out of the RV. Its direction is always perpendicular to the aorta and runs posteriorly and to right.

Both the vessels should be traced further to see the aorta curving round and pulmonary trunk bifurcating. It is necessary to confirm ventriculoarterial concordance where morphological RV gives out the pulmonary trunk and morphological left ventricle gives out the aorta. Confirming crossing over of two outflow tracts is very important.

**THREE VESSEL VIEW**

Three vessels are seen running posteriorly and to left. From forward left to rear right pulmonary trunk and aorta, which are in long axis and superior vena cava (SVC) which is seen in transverse/oblique section. The vessels show reducing caliber from pulmonary trunk to SVC. On color Doppler the direction of flow is same in aorta and pulmonary trunk in this view normally. Reversal of pulmonary trunk to aortic caliber ratio suggests pulmonary stenosis.

Three vessel trachea section (Fig. 12) shows aorta and pulmonary trunk getting close to join by ductus arteriosus, forming a “V”. Ductus arteriosus is seen as a vessel running posteriorly to the left of the spine from the bifurcation of the pulmonary trunk.

Slight higher level also shows trachea, just anterior to the spine. Slight sweep of the transducer shows the right and the left pulmonary artery (PA).

Sliding the probe transverse further upwards shows aortic arch in transverse section with trachea in the concavity of “c”. Slight caudal and left tilt from this shows aortic arch and duct together, with thymus anterior to the great vessels.

**SHORT AXIS VIEW**

As described in Yagel’s technique it shows aorta in the center in transverse section and pulmonary trunk with bifurcation surrounding it which is also known as circle and sausage view. A section taken little inferior to this will show aortic root in the center protected by a complete circle formed by the RV with its inflow and outflow tracts. This view may be used for detection of subpulmonary VSD (Fig. 13).
ARCH/LONGITUDINAL VIEWS

- Aortic arch view (Fig. 14) can be achieved by rotating the probe 90° from the transverse aortic arch view.
- Ductal arch (Fig. 15) can be seen by rotating the probe 90° from ductus arteriosus in transverse view.

On this section, heart is seen as a three chambered structure and aorta is seen arising from the middle chamber—Left ventricle and is cane/"U" shaped. It gives off three neck vessels from the transverse part of the arch. Ductus arch is seen arising from the anterior most chamber—RV of the heart and is hockey shaped/flat. Both the arches can be seen connecting to each other, forming a "Y" anterior to the spine.

Right atrium inflow tracts: Angulating the probe a little towards fetal right side from this view shows SVC and inferior vena cava (IVC) entering the RA.

Color Doppler is used for difficult to image patients when gray scale image quality is not very good and for diagnosis of flow abnormalities. It has also been used to potentiate the diagnosis made on gray scale. Color Doppler is especially useful for ventricular septal defects, stenosis, coarctation of aorta, ventricular hypoplasias and ductus dependent diseases. Power Doppler is used to evaluate the septal defects when four chamber view is transverse. It also gives better edge definition.

Pulse Doppler is used to find absolute velocities and to diagnose regurgitation or stenosis of the valves. Each vessel and each valve has a particular flow pattern. This can be seen as a particular shape of waveform on pulse Doppler. To diagnose abnormalities in flow we need to know the normal waveform/signature for that particular vessel and normal velocities.

Normal velocities:
Outflow tracts: 60–70 cm/sec
Ductus arteriosus: 90–135 cm/sec in systole and 15–25 cm/sec in diastole.

Normal waveform through the atrioventricular valve (Fig. 16) is double peaked forward flow where the first one E-wave represents filling of the ventricle by atrial contraction with no reverse flow through out the cardiac cycle.

Outflow tracts show systolic single peaked forward flow due to ventricular systole. Studying and understanding these waveforms can also inform us about cardiac function.

M-mode: It is used to demonstrate arrhythmias, measure atrial and ventricular size and size of the outflow tracts.

Study of four chamber view can be considered complete only when it is studied with gray scale, color and pulse Doppler and M-mode.

Before discussing the abnormalities of the heart it is essential to understand the normal fetal circulation. This will help us to analyze the findings seen on fetal echocardiography and to arrive to a diagnosis.

FETAL CIRCULATION

Inferior and SVC bring unsaturated blood from lower and upper part of the body to RA. Saturated blood from umbilical vein enters ductus venosus. This is a trumpet shaped branchless structure with the narrowest part only 2 mm in diameter and opens into the RA. The shape helps to create a high speed jet of blood, which is directed from the RA, through foramen ovale to LA, unmixed with the unsaturated blood. LA also receives blood from pulmonary veins. RV receives blood from RA and left ventricle from LA. RV gives out pulmonary trunk, which apart from right and left PA also gives out a third branch—ductus arteriosus. Left ventricle gives out aorta, which gives out coronaries and neck vessels in turn and then through ductus arteriosus it is connected to pulmonary trunk. This causes mixture of blood from pulmonary trunk and aorta which is ultimately supplied to the unprivileged lower half of the body. Because of any abnormalities in the heart the atrial changes precede the ventricular changes (Fig. 17).

Cardiac diseases are of multiple but classification according to the structure involved may make the understanding of these abnormalities easier.

![Fig. 16: Normal atrioventricular valve waveform](image)
CLASSIFICATION OF CARDIAC DISEASES
- Septal defects
- Right heart abnormalities
- Left heart abnormalities
- Conotruncal defects
- Single ventricle defects
- Other cardiac abnormalities
- Arrhythmias

SEPTAL DEFECTS

Interventricular Septal Defects
Interventricular septal defects are most common and consists of 30% of cardiac defects. They cause no hemodynamic disturbances in utero if not too large as in utero, pressures in both ventricles are similar and there is no significant shunting of blood. VSDs can be further classified according to their location on the ventricular septum (Figs 18A to C).

Muscular Defects
In muscular part of the septum (Figs 19A and B), lateral four chamber view is the best to diagnose these defects and shows drop out in septal shadow. But small defects are difficult to diagnose without color Doppler. On apical and basal four chamber view, the part of the septum close to the crux is often not seen. This must not be misinterpreted as septal defect. It is a defect only if the end of the septal line shows a thickened end.

Color Doppler may be used to define these defects. Even on color Doppler no turbulence will be seen as there is no pressure gradient between both chambers. The flow may be left to right, or right to left. 3D US image rendered in inversion mode has been successfully used to demonstrate even small VSDs.

Perimembranous Defects
This defect is in membranous septum, below aortic valve and may extend into the muscular part. It is seen only in long axis view below the aortic valve. LVOT view may demonstrate this defect (Fig. 20). They are most commonly malaligned and associated with conotruncal defects.

Inlet Defects
This defect is in the inlet part of the septum, close to AV valves’ septal insertion.

Subpulmonary Defects
This is seen at inflow part of the RV and affects implantation of septal chordae of tricuspid valve. It can be demonstrated only on short axis view below the pulmonary valve.

Small defects (< 3 mm) may close spontaneously. Forty-six percent of nonmaligned VSDs close in antenatal life and 23% during the first year of life. Only 31% remain patent. Malaligned defects are less likely to be corrected without surgery. Large muscular and large perimembranous defects and inlet and subpulmonary defects usually require surgery.

Atrial Septum Defects
It consists of 8% of congenital cardiac defects. Defects can be at three locations: (1) secundum; (2) sinus venosus; and (3) primum.
- Secundum defects are commonest but can not be diagnosed antenataly as are located at fossa ovalis. These may be isolated or with VSD/pulmonary valve stenosis. It is to be differentiated from foramen ovale thickening. Small defects may close spontaneously.
- Redundancy of the foramen ovale flap is known as aneurysm of foramen ovale commonly associated with atrial arrhythmias.
- Sinus venosus defects are difficult to diagnose. Five to ten percent of Atrial septal defects (ASDs) are sinus venosus defects, situated posterior to foramen ovale and inferior to superior vena cava.
- Primum defects are mostly a part of AV defect. ASDs do not require alteration in obstetric care.
Figs 18A to C: Ventricular septum anatomy
Abbreviations: Ao, aorta; CS, coronary sinus; DAO, descending aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle

Figs 19A and B: Muscular ventricular septum
Abbreviations: LV, left ventricle; RV, right ventricle
Atrioventricular Septal Defects

These are the defects of endocardial cushion causing primum ASD with VSD (Figs 21A to C). It may be associated with tetralogy of Fallot, double outlet RV, coarctation of aorta, ventricular hypoplasia subaortic or pulmonary valve stenosis. These defects are common with chromosomal abnormalities both aneuploidies and trisomies. The risk of recurrence is 7–17% in families with normal karyotype.11 Isolated defects have 85–90% survival rates after surgical repair.

On US complete AV septal defect will show single AV valve on four chamber view which is better demonstrated in diastole. In partial atrioventricular septal defects, both valves are attached at the same level to the septum instead of slight apical attachment of tricuspid valve normally. Color Doppler shows mixture of flow to ventricles. It is often associated with increased nuchal translucency. This anomaly can be diagnosed in late first trimester.

RIGHT HEART ANOMALIES

Tricuspid Valve Defects

Ebstein’s Anomaly

It is characterized by low placed tricuspid valve—septal and posterior cusps (Figs 22A and B). Due to this, RA appears enlarged but actually it is atrialization of RV, which is progressive in antenatal life. Color Doppler shows regurgitation into RA. Pulmonary trunk may be small/normal depending on the functional size of the RV. Severe right ventricular dysfunction may lead to severe pulmonary stenosis/ataresia, which is ductus dependent. Three vessel view shows reversal of pulmonary trunk to aortic ratio. It may often be associated with severe cardiac enlargement and lung hypoplasia. ASD may be associated with Ebstein’s anomaly. Other tricuspid valve abnormalities are:

- Thick, dysplastic tricuspid valve
- Unguarded tricuspid valve with almost no valvular tissue.12

Hypoplastic Right Heart/Pulmonary Valve Atresia with Intact Septum

Usually, the RV is small and hypoplastic with decreased contractility even in early gestation but may be progressive and may appear normal till 20 weeks. Interventricular septum is intact (Figs 23A and B).

Occasionally, RV may be enlarged and dysfunctional with dilated severely incompetent tricuspid valve. RA may be normal.

On color Doppler no forward flow is seen through tricuspid and pulmonary valve as both are atretic. On three vessel view aorta and pulmonary trunk show flow in opposite directions with turbulence at ductus as pulmonary trunk is filled through ductus arteriosus.13
Fetuses may develop cardiomegaly and hydrops due to cardiac decompensation. Termination should be offered for these fetuses.

**Pulmonary Stenosis**

There is thickening and doming of pulmonary valve. PA is small with increased Doppler velocities than in aorta causing turbulence. Septal defects are common. Reversed flow in ductus arteriosus is seen in ductus dependent disease, i.e. when pulmonary stenosis is critical.14

**Abbreviations:** LV, left ventricle; RA, right atrium; RV, right ventricle; TV, tricuspid valve

---

**Aortic Stenosis**

Aortic stenosis may be progressive in utero. Aortic valve is thickened and shows doming. Left ventricle may be hypertrophied and there also may be asymmetric septal hypertrophy usually. Thickening of the ventricular septum may obstruct the LVOT and cause subvalvular stenosis where valve may appear normal. These are not diagnosed in utero. Sometimes left ventricle may be dilated with decreased...
systolic function. Association with endocardial fibroelastosis is known.

Color Doppler shows increased flow velocity through aortic valve with turbulence and reversed flow seen in aortic arch.

Decreased velocity in aorta in these cases is suggestive of left ventricular failure. Mitral regurgitation is often present. Critical aortic stenosis is ductus dependent.

Coarctation of Aorta

Localized narrowing of the juxta ductal arch is known as coarctation of aorta (Figs 24 and 25). Most commonly this narrowing is between left subclavian artery and ductus arteriosus. Transverse arch and aortic isthmus appear small. Aorta appears smaller than pulmonary trunk on three vessel view. Because of this there is relative right ventricular and pulmonary trunk enlargement without right heart disease. On color Doppler, there is high velocity flow in proximal descending aorta.

Interrupted Aortic Arch

Aorta is not at all formed beyond the arch. The descending aorta is a continuation of ductal arch. This is a difficult diagnosis but the clue is straight ascending aorta on aortic arch view. Branches may or may not be present depending on the type of interruption (Figs 26A to C).

Hypoplastic Left Heart Syndrome

Left ventricle is small on four chamber view with poor contractility. LA may be small or normal in size. There is no forward flow through mitral or aortic valve. Aortic size and origin site are important for postnatal prognosis. Heart may appear normal at 16–18 weeks and disease may be progressive in utero. It is important to differentiate it from single ventricle (Figs 27A and B).

Mitral Valve Defects

Mitral valve defects are rare as isolated abnormalities. Blood flow turbulences on color Doppler are diagnostic.

CONOTRUNCAL DEFECTS

These are commonly associated with deletion of chromosome 22q11.2, which can be diagnosed by fluorescence in situ hybridization (FISH). This anomaly is associated with short stature, psychiatric problems and mild to moderate learning difficulties are common with cardiac defects.
Tetralogy of Fallot

It is the most common cyanotic heart defect and almost always missed if only four chamber view is obtained as cardiac screening. It has four components: (1) perimembranous VSD; (2) overriding of aorta; (3) pulmonary stenosis; and (4) hypertrophic RV. But the last component always becomes manifest only after birth. Obstetric management needs no change with isolated Fallot’s tetralogy (Figs 28A and B).

On US increased angle of cardiac axis is seen on four chamber view, which is otherwise normal. Long axis view shows VSD in the membranous part, with large aortic root. RVOT view shows small PA. Three vessel view shows inverse PA/Aorta ratio. Color Doppler shows increased velocity in PA due to RVOT obstruction and aorta is fed by two ventricles. Many a time only membranous VSD may be evident in early gestation.17

Double Outlet Right Ventricle

Both TGA arise from RV and depending on the site of origin; one of the two may show variable degree of stenosis. When both arteries are arising side by side, it is named as Taussig-Bing syndrome. Its differentiation from other outflow tract anomalies with large VSD may be difficult (Figs 29A to C).

On US deviation of cardiac axis may be present but four chamber view is otherwise normal. Anterior angulation from four chamber view shows parallel great vessels instead of crossing over of great vessels and is known as Taussig-Bing heart. VSD may or may not be present but color Doppler is confirmatory.

Truncus Arteriosus

Both the arteries arise as a single trunk from the ventricles. It is usually associated with a large VSD with the trunk overriding the septum. Types of truncus (Figs 30A and B):

On US increased cardiac axis is seen on otherwise normal four chamber view. Malalignment type large VSD is seen in outlet. Truncal root is seen arising from RV or overriding the septum. Abnormal truncal valve may or may not be present. The origin of PA must be confirmed to exclude pulmonary stenosis.

On color Doppler VSD is seen with origin of truncus overriding the septum. Origin of PA from the main trunk must be diagnosed. If dysplastic valve is present, it shows holodiastolic regurgitation on pulse Doppler.

Complete Transposition of Great Vessels

Aorta arises from RV and lies anteriorly and to left of pulmo- nary trunk and pulmonary trunk from left ventricle. This means two great arteries arise side by side at the base of the heart instead of crossing over of the great vessels (Figs 31A to C).
Figs 29A to C: Double outlet right ventricle
Abbreviations: Ao, aorta; RV, right ventricle

Figs 30A and B: Types of truncus arteriosus

Figs 31A to C: Complete transposition of great vessels
Abbreviations: Ao, aorta; LV, left ventricle; PA, pulmonary artery; RV, right ventricle
On US normal four chamber view is seen. Outflow tracts show parallel great vessels at the roots. There is no crossing over of vessels. Vessel arising out of LV takes posterior course and bifurcates so is PA. Vessel arising out of RV takes long upward course and curves. This is aorta. If associated with VSD and overriding, the diagnosis is difficult.

**Corrected Transposition of Great Vessels**

This is a very rare abnormality. RA opens into morphological left ventricle which gives out pulmonary trunk and LA opens into morphological RV and gives out aorta. These patients may have dextrocardia.

On US four chamber view shows deviated cardiac axis. Evidently normal looking heart shows ventricular inversion. AV discordance is confirmed by looking at the morphology of the chambers. Flap of foramen ovale opens in LA, which opens in a ventricle which is morphologically right containing chordae tendinea and moderator band. Great vessels do not show crossing over, but are parallel. Ventriculoarterial discordance can be confirmed by tracing the outflow tracts. Atrioventricular complete heart block may be seen on M-mode.\(^\text{18}\)

**SINGLE VENTRICLE DEFECTS**

Single ventricle defects are tricuspid atresia, single ventricle and heterotaxy syndromes.

**Tricuspid Atresia**

This defect is commonly associated with transposition of great vessels but chromosomal defects are rare in such fetuses.

On US single AV valve is seen. Tricuspid valve is absent/thick. RV is hypoplastic. RA is normal/large with restrictive ASD. Septal defects are common.

**Heterotaxy Syndromes**

Heterotaxy syndromes are rare. These should be suspected when there is abnormal disposition of thoracic and abdominal organs also. Descending aorta and IVC are on same side. IVC is interrupted and large azygos vein may open into SVC. Complex cardiac lesions are associated. Viscero-cardiac heterotaxy may/may not be present. Fetal hydrops may develop and may have up to 100% in utero mortality with heart block.

**OTHER CARDIAC DEFECTS**

Other cardiac defects are anomalous PV drainage, ectopia cordis, cardiomyopathies, endocardial fibroelastosis, cardiac tumors, obstructed foramen ovale, premature constriction of ductus arteriosus and absent ductus venosus.

**Abnormal Pulmonary Venous Drainage**

Normally, two out of four pulmonary veins can be seen entering LA on four chamber view after 18 weeks. Anomalous PV drainage may affect one or more of these veins. If all the four are involved it is total anomalous PV drainage, otherwise it is partial. Only total anomalous drainage can be excluded antenatally. Pulmonary veins instead of emptying into LA, may empty in RA or any other systemic veins. These may be portal-hepatic veins, innominate vein, SVC or coronary sinus. Total anomalous PV drainage has obligatory right to left atrial shunt (Fig. 32).

On US no pulmonary veins seen on four chamber view entering the LA. PV confluence is seen behind the RA. RV is large, if total anomalous PV drainage is present, but enlargement is not seen if there is ASD or infradiaphragmatic drainage. Color Doppler may show the PV drainage precisely.

**Ectopia Cordis**

**Thoracic Type**

Heart protrudes from the chest cavity with cephalic orientation of the cardiac apex.

**Thoracoabdominal Type**

Pericardium and diaphragmatic defects are present and heart is displaced into the abdomen.
Myocardial Diseases

Hypertrophic Cardiomyopathy

Thickened less contractile heart, it is seen in diabetic mothers and may cause LVOT obstruction.

In dilated cardiomyopathy there are dilated ventricles with decrease systolic function and cardiac failure.

Fibroelastosis

Thickening of ventricular endocardium with bright echogenic shadows are seen on US with decreased systolic function (Fig. 33).

Both these conditions can lead to cardiac failure and hydrops.

Obstructed foramen ovale: Commonly associated with left heart obstructive defects. It may also be associated with mitral regurgitation, supraventricular tachycardia or fetal hydrops.

This can lead to prenatal right heart failure, hydrops and fetal death. Postnatally, it leads to persistent fetal circulation, right heart failure and death.

Cardiac Tumors

Rhabdomyomas are most common. They may be associated with tuberous sclerosis and may be multiple. It can be detected as early as 20 weeks of gestation and are progressive. They are seen as solid intracardiac tumors and show movements with cardiac cycle. Depending on size and position, they may cause obstructive defects, cardiac failure or arrhythmias. Others are fibromas, teratomas, myxomas and hemangiomas. Fibromas are usually solitary and commonly arise from left ventricular apex. Though usually homogenous may sometimes have cysts or calcifications.

Premature Constriction of Ductus Arteriosus

Use of indomethacin may lead to ductal obstruction between 28 weeks and 34 weeks. Evaluation for the same is to be done within 48–72 hours of starting indomethacin. Total ductal closure may be associated with fetal demise. Ductal arch patency must always be checked when doing a fetal echocardiography. Ductal obstruction will lead to RV enlargement, hypertrophy, RA enlargement and TR and ultimately may lead to right heart failure.

On pulse Doppler normal velocity in ductus arteriosus is 150 cm/s (Sys), 40 cm/s (Dias.). Its constriction causes higher systolic and diastolic velocities. Only high systolic velocity may be seen in last 4–6 weeks and in conditions with increased fetal cardiac output, but high diastolic velocity is diagnostic of ductal constriction.

Obstructed Foramen Ovale

It is commonly associated with left heart obstructive defects. It may also be associated with mitral regurgitation, supraventricular tachycardia or fetal hydrops. Prenatal death may occur due to right heart failure, hydrops and death.

Absence of ductus venosus: Umbilical vein is connected to either IVC or renal vein leading to significant dilatation of IVC since midgestation. Umbilical vein takes an inferior course. A long aberrant vessel is seen from liver to right abdominal wall crossing the diaphragm.

ARRHYTHMIAS

Arrhythmias must be always confirmed by M-mode.

Tachycardia

It is twice common than bradycardias. Tachycardias due to maternal fever, drugs, thyrotoxicosis, fetal distress or infection range from 180 beats/minute to 200 beats/minute. Those due to supraventricular tachycardia heart rates are 220–260 beats/minute. Atrial flutter gives heart rate of more than 300 beats/minute. Ventricular tachycardia may occur due to perinatal stress and hypoxia, cardiomyopathy, drug intoxication, electrolyte imbalance and ventricular aneurysm.

Bradycardia

Bradycardias are most likely due to heart blocks, which are often regular, 2:1 or variable. It is commonly associated with major cardiac defects or maternal anti-SS-A and anti-SS-B antibodies.

Irregular Rhythm

Arrhythmias are commonly associated with obstructed foramen ovale, cardiac tumors, cardiomyopathy, Ebstein’s
anomaly and atrial septal aneurysm. It can occur due to maternal ingestion of caffeine, Hydrazine, Nifedipine and are reversible after stopping drugs.

Fetal echocardiography must be included in the detailed structural scan in second trimester routinely and must be offered with nuchal scan or at least at 16–18 weeks for all the high-risk fetuses.

REFERENCES

DEFINITION AND BACKGROUND

The genetic sonogram is an ultrasound examination done on second trimester fetuses that not only evaluates the fetus for structural malformations, but also searches for the sonographic markers of fetal Down’s syndrome.1 Most workers have extended the definition to the second trimester fetal anatomic survey targeted at identifying features associated with any aneuploidy.2-5 It has evolved as an adjunctive screening tool capable of further refining the individualized risk-calculation for trisomy that is based on maternal age or serum screening markers.6

The common aneuploidies include trisomy 21 (Down’s syndrome), 13 (Patau syndrome) and 18 (Edwards syndrome), Turner’s syndrome (XO) and triploidy. Other aneuploidies are rarer and are encountered most frequently in abortus karyotypes. Trisomy 21 is associated with potential long-term morbidity and has an estimated prevalence of 1.21 per 1,000 live births.7 Trisomy 13 and 18 usually abort spontaneously or result in intrauterine demise, and, if born alive, rarely survive beyond the neonatal period. The greatest emphasis in the genetic sonogram, therefore, is to screen the population and then follow-up with an appropriate definitive diagnostic procedure for Down’s syndrome.

Screening procedures refer to tests that define an at-risk population and diagnostic tests refer to an actual demonstration of fetal karyotype. Screening tests for aneuploidies include maternal age, serum markers and ultrasound markers. The chromosomes themselves can be demonstrated by karyotyping of cells from amniotic fluid, chorionic villi or fetal cord blood or by identifying an abnormal karyotype by fluorescent in situ hybridization (FISH) or quantitative fluorescent polymerase chain reaction (QF-PCR) studies.

Although, the incidence of Down’s syndrome increases with increasing maternal age particularly beyond 35 years, 80% of Down’s syndrome babies are born to women younger than 35 years.1 The prevalence of trisomy 21 decreases with increasing gestational age, being about 30% higher at 16–20 weeks’ gestation compared with term8 and about 48–50% higher at 9–14 weeks compared with term.9

Soon after the finding of an association between low maternal serum alpha-fetoprotein (MSAFP) and Down’s syndrome, it was discovered that the addition of an assessment of maternal serum unconjugated estriol (E3) and beta human chorionic gonadotropin (β-hCG) in the form of the “triple test” was an effective screening test in women under 35 years of age with a sensitivity of 57% and a false positive rate of 3.25%.10

In recent years, improved resolution of ultrasound and its consequent ability to demonstrate abnormal morphology, have placed the sonographic examination in a more sensitive and specific position than maternal age and maternal serum screening. This is very significant in the perspective of the observation that amniocentesis for prenatal detection of chromosomal aneuploidy, a diagnostic tool offered at one time arbitrarily to all pregnant women aged 35 years or over, has in recent years lost favor as a first-line investigation.6 This shift in practice stems from a recognition that selection of candidates for amniocentesis for prenatal detection of chromosomal aneuploidy, a diagnostic tool offered at one time arbitrarily to all pregnant women aged 35 years or over, has in recent years lost favor as a first-line investigation.6 Furthermore, the well-established iatrogenic fetal loss rate associated with amniocentesis, although low (less than 1%), is increasingly being regarded by patients as unacceptable, particularly when the vast majority of apparently at-risk pregnancies are chromosomally normal.6 Patient access to information from professional medical counseling, the internet, and guide-
books, has put forth a demand for combining maternal age, maternal serum screening and sonographic findings in order to provide individualized patient-specific risk estimates and refine selection criteria for amniocentesis.\textsuperscript{12,13} The manner in which ultrasound information can be utilized to optimize obstetric decision-making in clinical practice is presented here.

\begin{center}
\textbf{SONOGRAPHIC MARKERS FOR DOWN’S SYNDROME (TRISOMY 21)}
\end{center}

Neonatologists have for many years used morphological features to identify Down’s syndrome. These include a flat facial profile, epicanthal folds, short stature, a mongoloid eye slant, muscle hypotonia, a single palmar crease, and excess skin over the back of the neck, hypoplastic middle digit of the fifth phalanx, sandal gap foot deformity, flat iliac wings, duodenal atresia and heart defects. Sonologists have extended morphological feature recognition to identify those fetuses at high risk for trisomy 21 using a combination of major anomalies, major markers and minor markers.

\section*{Overview of Markers}

Major anomalies are seen in about one-third of affected fetuses and include heart defects particularly ventricular septal defects and atrioventricular septal defects, ventriculomegaly, cystic hygromas, omphalocele and hydrops. Major markers include a thickened nuchal skin fold, short femur, short humerus, echogenic intracardiac focus, echogenic bowel and renal pyelectasis. Minor markers include flat iliac wings, brachycephaly and frontal lobe shortening, clinodactyly, sandal gap great toe deformity, short ear length, cerebellar hypoplasia and a single palmar crease.

A few of these features represent actual structural abnormalities that have clinical consequences regardless of karyotype. Most, however, are considered traits or markers that often have no serious clinical importance with the exception of their relationship with aneuploidy. To make matters more complicated, these features may be transient, resolving by the third trimester of gestation.\textsuperscript{14-16}

\section*{Major Markers}

A thickened nuchal skin fold was the first major marker identified for trisomy 21.\textsuperscript{17} This remains the most useful marker to date. This is measured in an axial plane through the posterior cranial fossa and calipers are placed corresponding to the outer surface of the occipital bone and the outer surface of the skin. A thickness of more than 5 mm is significant before 18 weeks of gestational age and a thickness exceeding 6 mm beyond 18 weeks.\textsuperscript{18-20}

\textit{Although echogenic bowel is often a normal variant in the second trimester, one in eight fetuses with Down’s syndrome show this feature.}\textsuperscript{21-23} Bowel should be labeled echogenic only if it is brighter than adjacent bone. It also needs to be remembered that high frequency transducers and equipment with real time enhanced contrast resolution and speckle reduction software options accentuate brightness of bowel. Bowel may also be echogenic in fetuses with cystic fibrosis, mesenteric ischemia and cytomegalovirus infections. Fetuses that swallow blood from a placental bleed also show increased bowel echogenicity consequent to ingested heme pigments.

\textit{The echogenic intracardiac focus (EIF) refers to calcified papillary muscle that is seen as a bright dot on ultrasound. This is usually in the left ventricle but occasionally in the right ventricle or both ventricles. It should be as bright as bone. 16\% of fetuses with trisomy 21 and 395 of fetuses with trisomy 13 demonstrate this feature.}\textsuperscript{16,24,25} The risk for trisomy is higher if the echogenic focus is in the right ventricle or both ventricles. The prevalence of this marker in normal fetuses is as high as 30\% in normal fetuses of Asian ethnic origin.\textsuperscript{36} As an isolated marker, therefore, it does not warrant further investigation. An EIF is not associated with cardiac anomalies in low-risk patients.\textsuperscript{15}

\textit{Pyelectasis} refers to an increase in the anteroposterior diameter of the renal pelvis beyond 4 mm at 15–20 weeks of gestation. Twenty to twenty-five percent of fetuses with Down syndrome demonstrate this feature.\textsuperscript{57-25} In isolation, this marker is not an indicator for amniocentesis. It should be used in conjunction with other markers.

Short humerus and short femur are defined as an observed-to-expected length of less than 0.9.\textsuperscript{34,38} The expected bone length is based on a biparietal diameter measurement. Expected femur length = – 9.3105 + 0.9028 × BPD. These have been identified as markers for trisomy 21 and are useful when combined with other markers.\textsuperscript{21} A short humerus is more sensitive as a marker than a short femur.\textsuperscript{32} Both these markers are limited by the requirement of data specific to the population being studied and by ethnic diversity. Femur/foot length ratio, although useful in assessing skeletal dysplasias are not useful in assessing for Down’s syndrome.\textsuperscript{31}

\section*{Minor Markers}

A widened iliac angle has been observed in children with Down’s syndrome and this has been extended to assessing the iliac angle in the fetuses.\textsuperscript{33,34} The increase in angle represents an increased distance between the iliac crests and should be measured in a transverse view of the spine. The mean iliac angle is 80 ± 19.7° in normal fetuses of 21 and 63.1 ± 20.3° in normal fetuses. The technique of measurement is cumbersome and limits routine use of this marker.\textsuperscript{63.1 ± 20.3°} Clinodactyly refers to hypoplasia of the middle phalanx of the fifth digit and is a morphological feature of children with trisomy 21 and can be seen in the fetus as well.\textsuperscript{3} Although initially regarded with skepticism, this marker has performed well and shows a sensitivity of 17.1\% and a false positive rate of 3\%.\textsuperscript{25} A wide space between the first and second toes is seen more frequently in trisomy 21 fetuses and is called a
sandal gap toe deformity. The reliability in various studies is variable. Nasal bone hypoplasia is a high sensitive and specific marker for trisomy 21. It is a feature of 62% of trisomy 21 fetuses and approximately 1% of chromosomally normal fetuses. The nasal bone was initially considered to be hypoplastic if it was either absent or strikingly small (less than 2.5 mm). Later data has described the nasal bone length increasing with gestation from a mean of 4.7 mm at 15 weeks to 8.2 mm at 22 weeks and such normative data is likely to be more specific in assessing this marker. The efficiency of using various nasal bone criteria for the detection of aneuploidy has been studied further and it has been observed that the optimal nasal bone threshold associated with trisomy 21 was a biparietal diameter/nasal bone length ratio of 11 or greater. An important prerequisite to consider when using this marker is the angle of insonation of the fetal nose, which should be between 45° and 135° to avoid false shortening. Brachycephaly in fetuses with trisomy 21 reflects a frontal lobe shortening and has been assessed in several studies. The frontothalamic distance was less than the 10th centile in 52% of fetuses with trisomy 21. Short ear length, cerebellar hypoplasia and amniodecidual separation have been described in literature but their reliability is questionable.

**Sensitivity of Marker Detection**

There is a wide variation in the detection rates of sonographic markers of trisomy 21. Strict standardization of definitions, operator experience and dedication can largely overcome this.

Other variables that influence detection rates include gestational age and maternal body habitus. The detection rate rises from 1 in 8 at 15 weeks of gestation to greater than 60% after 18 weeks. Serial reviews are, therefore, to be considered if the maternal abdomen is fat and hirsute and if the genetic sonogram is performed prior to 18 weeks of gestation. Pelviectasis is more frequently picked up in male fetuses.

**Significance of Individual Markers**

The accuracy of the genetic sonogram and the significance of each marker has been evaluated in several studies. All studies refer to the presence of major structural anomaly, soft markers or both. Identification of at least one marker conferred an overall sensitivity of 72–77% with a false positive rate of about 13%.

Significantly, about half of all fetuses had a nuchal fold thickness of 5 mm or more rendering this the most sensitive individual marker. The risk of trisomy 21 increases with the number of markers detected. The prevalence of isolated and multiple markers has been evaluated. In this analysis of 186 fetuses with trisomy 21, an isolated soft marker was identified in 22.6% of cases and 11.3% of euploid controls, while two or more markers were observed in 15.1% of cases and just 1.6% of normal controls.

The greatest challenge in risk assignment is where a marker is identified in isolation. If isolated soft markers are used as a basis for deciding to offer invasive testing, the resultant fetal loss rate would exceed the number of cases of trisomy 21 detected and indeed, that detection rates would fall. This assertion has been challenged by others who argue that while this may confirm the poor contribution that isolated soft markers make to risk assignment for aneuploidy, the performance of combined markers has been well validated in screening paradigms and furthermore, that dismissal of the role of soft markers in screening ignores the pivotal role their absence plays in providing patient-reassurance and avoiding invasive testing. The unacceptably high false-positive rate associated with identification of isolated soft markers in low-risk women presents a challenge insofar as there will always be a group of low-risk women undergoing “routine” mid-trimester sonography, in whom soft markers for aneuploidy may not be actively sought but may be incidentally noted. For this several scoring systems have been devised which correlate maternal age, serum biochemistry and sonographic markers.

A simple sonographic scoring index for the detection of chromosomal aneuploidy was devised by Benacerraf et al. Major structural anomalies and a thickened nuchal fold were each given a score of 2, as these are sufficiently strong even when detected in isolation. Soft markers were each allocated a score of 1. The panel of soft markers included: Short femur, short humerus, pylecasis, echogenic intracardiac focus (EICF), echogenic bowel, and choroid plexus cysts. The authors demonstrated that, where amniocentesis was reserved for fetuses scoring greater than or equal to 2, 73% of fetuses with trisomy 21 and 85% of fetuses with trisomy 18 could be identified with a false positive rate of 4%. Using likelihood ratios, two approaches have been proposed by Nyberg and Nicolaides to calculate a revised risk. The Nyberg method involves multiplication of the a prior risk by the likelihood ratio (LR) associated with any identified marker or markers. The latter calculation, proposed by Nicolaides, further takes into account the negative likelihood ratios associated with absent markers. The practical application of these two approaches in fact yields similar results. For example, a 39-year-old woman has an a priori age-related trisomy 21 risk of 1 in 100. The genetic sonogram identifies an isolated thickened nuchal fold. Applying the Nyberg method, the LR associated with this marker is multiplied by her a priori risk (0.01) to give a revised risk of 0.01 × 11 = 0.11, or 1 in 9. Applying the Nicolaides method in the same scenario requires multiplication of her a priori risk by a positive LR of 53.1 associated with nuchal fold thickening and also by the negative LRs associated with absent markers (i.e. combined negative LRs 0.7 × 0.9 × 0.6 × 0.9 × 0.8 = 0.272) associated with the absence of short humerus, echogenic bowel, short femur, pylecasis, and EICF, respectively). The same woman’s revised risk is computed by multiplying these risks (0.01 × 53.1 × 0.272) to arrive at a risk of 0.14 or one in seven. It is worth noting the consistently wide confidence intervals...
surrounding the point estimates of these likelihood ratios, inferring that while the identification of one or more markers is an effective screening tool, the actual computed risk is only an approximation.

**TRISOMY 18 (EDWARDS SYNDROME)**

Ninety percent of fetuses with trisomy 18 have an abnormal early second trimester morphology and up to 100% have an abnormal third trimester morphology. 

*Common stigmata include:* Choroid plexus cysts, ventriculomegaly, strawberry shaped skull, a large cisterna magna, agenesis of the corpus callosum, meningomyeloceles, microphthalmos, hypertelorism, low set ears, cystic hygromas, thickened nuchal skin fold, cardiac defects, diaphragmatic hernia, renal anomalies, omphalocele, short radial ray, clenched hand with overlapping fingers, rocker bottom foot, club foot, polyhydramnios, intrauterine growth restriction (IUGR) and a single umbilical artery, umbilical cord cysts and absent end diastolic umbilical artery flow velocity waveforms.

Ultrasound is often used to detect trisomy 18 when the triple screen shows a low alpha fetoprotein, low β-hCG and low free estriol. In addition, when choroid plexus cysts are present the search for other stigmata should be intensified. Isolated choroid plexus cysts do not warrant an amniocentesis for karyotyping.

**TRISOMY 13 (PATAU SYNDROME)**

Morphologic abnormalities are evident from 10 weeks onward and the sensitivity is 90–100%. It is very unusual for an affected fetus not to have a morphological stigma. Features include holoprosencephaly, agenesis of the corpus callosum, ventriculomegaly, enlarged cisterna magna, microcephaly, microphthalmia, hypertelorism, cyclopia, proboscis, cleft lip and palate, midline facial hypoplasia, nuchal thickening, cystic hygroma, cardiac defects, neural tube defects, echogenic enlarged kidneys, echogenic bowel, echogenic intracardiac focus, omphalocele, cystic kidneys, radial ray aplasia, polydactyly and a single umbilical artery.

**TURNER’S SYNDROME (XO)**

This is a syndrome consequent to the loss of an X chromosome, usually paternal. Most fetuses are spontaneously aborted. Ongoing pregnancies are characterized by extensive, often whole body, septated cystic hygromas which may regress over time and persist as only a webbing of the neck in an adult. Long-term survival is associated with a short stature, ovarian dysgenesis and occasionally mental retardation. It is also associated with left heart defects especially coarctation of the aorta and aortic valvular defects, horseshoe kidney and a short femur. There may be evidence of hydrops consequence to a high output cardiac failure. Mosaicism is common, often resulting in delayed menarche.

**TRIPOLOGY**

This occurs as a result of a complete extra set of chromosomes. Survival beyond 20 weeks of gestation is rare.

Features include severe early onset asymmetric IUGR, microphthalmia, hypertelorism, micrognathia, ventriculomegaly, midline brain defects, cystic hygromas, omphaloceles, renal anomalies, an enlarged placenta, oligoamnios, and abnormal umbilical artery flow velocity waveforms.

**GENETIC SONOGRAPHY AFTER FIRST TRIMESTER SCREENING**

First trimester genetic screening is now widely available and involves assessing maternal serum biochemistry and sonographic markers in order to identify patients who should undergo invasive testing. This is carried out between 11 and 13 weeks 6 days of pregnancy and has the advantage of an easier and safer termination of pregnancy and less parental psychological trauma. The combination of maternal serum pregnancy-associated plasma protein A (PAPP-A) and free hCG along with fetal crown-rump length to assess fetal size and a group of ultrasound markers allows detection of 88–90% of fetuses with Down’s syndrome. The ultrasound markers include nuchal translucency thickness, nasal bone delineation, fetal ductus venosus studies and fetal tricuspid regurgitation. Additional ultrasound markers include frontomaxillary facial angle, fetal growth, fetal heart rate, megacystis, cardiac anomalies and micrognathia.

In this group of patients sequential screening with a second trimester genetic sonogram enhances the detection rate for Down’s syndrome to 94–96%.

SECTION

INTRODUCTION
The ultimate goal of prenatal diagnosis (PND) has always been to find a “cure”, not just the termination of pregnancy (TOP), or sometimes the birth of a sick diseased child to be salvaged by often futile postnatal treatments. Fetal treatment (or fetal therapy) is the “operative branch” of fetal medicine. It includes a series of interventions performed on the “sick” fetus with the aim of achieving optimal fetal well-being. These interventions include medical and surgical procedures. As more sophisticated tests of PND are becoming available, the desire and demand for fetal therapy is getting more and more precious and necessary.

Some of the conditions affecting various organ systems amenable today to in utero treatment are listed. There are, however, several ethical and social factors that should be considered while recommending the options. The fetal status has to be assessed accurately, in consultation with geneticist, radiologist, neonatologist, pediatric surgeon, cardiologist, microbiologist the Fetal Medicine Team. Parents have to be counselled on maternal/fetal risk, type of interventions, cost, hospital stay, etc. Cases are best referred to few super specialized centers with the necessary expertise, early.

MEDICAL FETAL THERAPY
In general, a medical intervention is performed by administering medication to the mother where in the drug crosses through the placenta and reaches the blood circulation of the fetus, or, the medication is given directly to the fetus usually through an ultrasound (US)-guided approach.

THYROID

Hypothyroidism
In the absence of maternal thyroid disease, or iodide-induced hypothyroidism, fetal goiter is extremely rare. Ultrasonographic features are presence of echogenic masses in the fetal neck (goiter), polyhydramnios and hypothyroidism diagnosed based on raised fetal serum thyroid-stimulating hormone (TSH) levels obtained by percutaneous umbilical blood sampling (PUBS).

Treatment
It involves series of intra-amniotic injections with triiodothyronine (T₃) or with levothyroxine (250–500 µg weekly). Shrinkage of the fetal goiter, increasing neck flexion and resolution of the polyhydramnios assures improvement. Following birth, neonatal serum TSH levels indicate dose of thyroxine (T₄).¹ In utero, therapy may not only reduce the obstetric complications associated with large goiters, but possibly improve the prognosis for normal growth and mental development of affected fetuses.²

Hyperthyroidism
This is usually secondary to maternal Graves’ disease or Hashimoto’s thyroiditis. Congenital hyperthyroidism is less frequent than hypothyroidism. During fetal life tachycardia, cardiac arrhythmia, growth restriction and prematurity are the consequences. Postnatal signs of hyperthyroidism are
irritability, tachycardia, hypertension, poor weight gain and thyroid enlargement. Even cardiac failure may occur if hyperthyroidism is severe and treatment not adequate which explains the high early mortality rate of 16%. The main complication of persistent hyperthyroidism in the neonatal period and during infancy is craniosynostosis. Severe developmental delay or even mental retardation can be the consequence of inadequate high T₄-levels during fetal and neonatal life.

It is of utmost importance to scrutinize fetal thyroid by ultrasonography and to have a team work with obstetricians and pediatric endocrinologists in pregnant women with Graves’ disease. Cord blood sampling allows confirmation of fetal status.

**Treatment**

Treatment is maternal propylthiouracil (PTU) 50–100 mg orally three times a day, or with methimazole.³,⁴

**CONGENITAL ADRENAL HYPERPLASIA**

Congenital adrenal hyperplasia due to enzyme deficiency in steroid biosynthesis most commonly 21-hydroxylase triggers excessive androgen production before birth. Affected females may have genital ambiguity, experience virilization both physically and psychologically. PND and treatment of congenital adrenal hyperplasia has been implemented for more than 20 years, through biochemical or molecular genetic analysis of fetal deoxyribonucleic acid (DNA) by amniocentesis or using chorionic villus sampling.

**Treatment**

In families at risk, prenatal maternal dexamethasone therapy is started at a gestational age of 6 weeks in a median dose of 20 mg/kg/day. PND by chorionic villus sampling at 10–12 weeks or amniocentesis at 16–18 weeks should be performed. In the female affected fetus, continued appropriate dexamethasone administration to the pregnant mother is necessary to reduce genital virilization in the fetus. This spares the newborn female the consequences of genital ambiguity, genital surgery, sex misassignment and gender confusion.

Current data from large human studies show the benefit and safety of prenatal treatment.⁵-⁸ Long-term follow-up of the safety of prenatal treatment is currently underway. This practice is a rare example of effective prenatal treatment to prevent a malformation caused by an inborn error of metabolism. In one series, 53% reported maternal adverse events, 8% observed adverse fetal events.⁵ There is need for further improvement in PND and treatment, compliance during puberty, screening programs, psychological aspect and corrective surgery.

**NONIMMUNE HYDROPS**

Nonimmune hydrops fetalis (NIHF) is used to describe fetuses and newborns with generalized edema or at least two cavity effusions. The prognosis of hydrops fetalis differs markedly between different etiological groups. Etiologies range from treatable causes with a good outcome and probably no long-term side effects [as in case of parvovirus B19 (PVB19)] to others which are incompatible with life or associated with considerable perinatal morbidity and mortality. A thorough maternal-fetal work-up will dictate treatment of the cause.

The rate of PVB19 infection in cases of “idiopathic” NIHF is reported to be approximately 16% with polymerase chain reaction (PCR)-based methods.³ Late (third-trimester) cases of “idiopathic” NIHF are likely to be negative by all methods, either because they are not attributable to PV infection or because PV protein and DNA are below detectable levels or are no longer present. Maternal serology for PV and TORCH (Toxoplasmosis, Rubella, Cytomegalovirus, Herpes simplex, Syphilis) agents may be the best method for investigating third-trimester losses to otherwise unexplained NIHF.

In one study, of 55 cases of NIHF,²⁸ eight (14.5%) were due to human PVB19 infection, 14 cases (25.5%) were associated with aneuploidy and four (7.3%) had primary hydrothorax. A cardiac cause was found in five (9.1%) cases: three had supraventricular tachycardia (SVT), one had congenital complete heart block. Cystic hygroma was associated with hydrops fetalis in six cases. Twin-twin transfusion syndrome (TTTS) was the cause for hydrops in two cases. Massive transplacental hemorrhage was identified in one case. Fetal akinesia and muscular dystrophy caused hydrops in one case each. In 14.5% (8/55) of cases, no obvious cause was identified and these were classified as “idiopathic.” Three other cases could not be classified because parents declined investigations (unclassified). The outcome was favorable in only 27.3% (15/55) of cases.

Fetal hydrops following massive fetomaternal hemorrhage can be successfully managed by serial fetal intravascular transfusions (IVT).¹¹,¹²

Autopsy in conjunction with placental examination and fetal US represent the best combination to determine the etiology of NIHF among stillborn fetuses. In a study of 51 cases of NIHF,¹³ pertinent diagnoses were maternal diabetes mellitus,⁴ congenital heart disease,³ and cystic hygroma,³ one instance each of cardiac tumor, twin transfusion syndrome, congenital adenomatoïd malformation, syphilis, Turner’s syndrome and cerebral arteriovenous malformation.

Postmortem and placental examination confirmed the following etiologies: congenital infections;¹⁴ placcental pathology significant enough to explain NIHF:¹⁰ cardiovascular diseases⁸ (further classified as congenital heart disease,³ rhabdomyoma¹ and vascular malformations⁸); chromosomal abnormalities⁶ uncontrolled maternal
diabetes;\textsuperscript{4} intrathoracic lesions\textsuperscript{2} prune-belly syndrome;\textsuperscript{2} and idiopathic NIHF.\textsuperscript{2} Only 3.9\% of the cases studied had no identifiable etiology. The cause of hydrops was confirmed by autopsy in 47 fetuses (92\%), which further supports the importance of performing an autopsy. Thirty-two cases (62.74\%) had placental abnormalities helpful to the etiology (PV, syphilis, Turner’s syndrome, etc.).

**INBORN ERRORS OF METABOLISM**

Inborn errors of metabolism are rarely amenable to fetal therapy.

**Maternal Phenylketonuria**

Maternal phenylketonuria (PKU) can result in multiple congenital anomalies. As the cohort of young women with treated PKU is growing steadily, maternal PKU is going to become an even greater cause for concern.

**Treatment**

Maternal dietary control should be established before conception. Most problems occur when dietary control is not established until after the second trimester. Women with PKU must follow a strict low-phenylalanine diet aimed at controlling blood phenylalanine to 120–360 µmol/L, during pregnancy in order to protect the fetus from the deleterious effects of high maternal blood phenylalanine.\textsuperscript{15}

Dietary control was established before conception in 17 pregnancies (44\%). Five mothers with hyperphenylalaninemia had 11 pregnancies.\textsuperscript{16} There were no congenital anomalies in this group, and all appeared to be developing normally. Fifteen women with classical PKU had 28 pregnancies. One pregnancy ended in a first-trimester miscarriage. Twelve out of twenty-seven (44\%) completed pregnancies produced babies with a congenital anomaly and/or developmental delay.

**3-Phosphoglycerate-dehydrogenase Deficiency**

3-phosphoglycerate-dehydrogenase (3-PGDH) deficiency is an L-serine biosynthesis disorder, characterized by congenital microcephaly, severe psychomotor retardation and intractable seizures. PND of an at-risk pregnancy is by DNA mutation analysis. 3-PGDH deficiency is an inborn metabolic error that can be successfully treated antenatally.

**Treatment**

*L-serine therapy*: In one case report, US assessment showed a reduction in fetal head circumference from the 75th percentile at 20 weeks gestation to the 29th percentile at 26 weeks.\textsuperscript{17} L-serine was given to the mother, which resulted in an enlarged fetal head circumference to the 76th percentile at 31 weeks. At birth, the girl’s head circumference was normal, and at 48-month follow-up, her psychomotor development has been unremarkable.

**ALLOIMMUNE THROMBOCYTOPENIA**

Fetomaternal alloimmune thrombocytopenia (FMAIT) is the most common cause of severe thrombocytopenia in term neonates but its management remains controversial. Human platelet antigen 1a (HPA-1a) antibodies are most commonly implicated in severe thrombocytopenia but HPA-5b and HPA-15b antibodies can also result in poor outcome.

**Therapy**

Use of *maternal therapy* as first-line treatment is recommended. It can be stratified on the basis of the sibling history of FMAIT—antenatal intracranial hemorrhage (ICH) or severe thrombocytopenia (platelet counts of < 20 × 10\(^9\)/L) have significantly lower pretreatment platelet counts than cases whose siblings had less severe thrombocytopenia or postnatal ICH.

**Serial Platelet Intrauterine Transfusions**

In one series, cases with maternal therapy resulted in a platelet count exceeding 50 × 10\(^9\)/L in 67\% of cases.\textsuperscript{14} None of the fetuses managed by serial platelet intrauterine transfusions (IUTs) suffered ICH following treatment. However, several serious complications arose with fetal blood sampling (FBS).

**Postnatal Transfusion**

Postnatal transfusion management is extremely variable and fetal transfusions are associated with significant morbidity. Of 123/200 (62\%) cases (two sets of twins) with no previous history of FMAIT, intrauterine deaths occurred in five: anti-HPA-1a alone, three; in combination with anti-HPA-5b, and one; with anti-HPA-15b.\textsuperscript{18} Of the 120 live neonates, 103 had severe thrombocytopenia and 17 (14\%) developed ICH (anti-HPA-1a, 13; anti-HPA-5b, three; anti-HPA-15b, one). Postnatal care varied widely with 37\% of neonates receiving random rather than HPA-1a and HPA-5b-negative platelets. Of the remaining 77 cases with a history of FMAIT, 40 received IUTs. Six (15\%) of these fetuses died in utero and an additional two developed ICH postnatally. Of the 19 children with ICH, one (anti-HPA-15b) died on Day +1, and neurologic sequelae persist in 13 (mean follow-up, 2.5 years).

**FETAL INFECTIONS**

**Parvovirus B19**

Most maternal infections with PVB19 occur through contact with infected children at home, and can cause several serious complications in the fetus such as fetal anemia, neurological
anomalies, hydrops fetalis and fetal death. Testing maternal serum for immunoglobulin M (IgM) antibodies against PVB19 and DNA detection by PCR can confirm maternal infection. If maternal infection has occurred, US investigation of the fetus and measurement of the peak systolic flow velocity of the middle cerebral artery are sensitive noninvasive procedures to diagnose fetal anemia and hydrops.

**Therapy**

Intrauterine transfusion is currently the only effective treatment to alleviate fetal anemia, but if the fetus is (near) term, induction of delivery should be considered. Fetal PVB19 infection may, however, induce central nervous system damage, and may, not, be related to the severity of fetal anemia and acidemia. A total of 25 IUTs were performed in 24 hydropic fetuses. Median fetal hemoglobin (Hb) concentration, platelet count and blood pH before IUTs were 4.5 g/dL (range: 2.4-11.4 g/dL), 79 x 10^9/L (range: 37-238 x 10^9/L) and 7.36 (range: 7.31-7.51), respectively. Of 16 survivors aged 6 months to 8 years, 11 children (68%) were normal, and five children (32%) demonstrated a delayed psychomotor development with suboptimal neurological examination (mild delay n = 3, severe delay n = 2). Neurodevelopmental status did not correlate with pre-IUT Hb, platelet, or blood pH values. Growth and general health status were normal in all. Two children had minor congenital defects. Neurodevelopmental status was abnormal in 5 of 16 survivors.

**TOXOPLASMOSIS**

Infections with *Toxoplasma gondii* occur worldwide, but are especially prevalent in Europe, South America and Africa. The primary problem for the diagnosis of *T. gondii* infection is longstanding IgM-antibodies, thus the presence of *T. gondii*-specific IgM-antibodies do not necessarily indicate an acute infection. The use of a Toxoplasma-specific IgG-avidity ratio, differentiated Western blots and two-dimensional immunoblots usually resolves diagnostic problems. There is no consensus on the best strategy to control congenital toxoplasmosis. Despite 3 decades of prenatal screening for congenital toxoplasmosis in some European countries, uncertainty remains about the effectiveness of prenatal treatment. Without treatment, congenital toxoplasmosis has recurrent, recrudescence and adverse outcomes. TOP is usually recommended to pregnant women who have infection with *T. gondii* before 26 weeks of pregnancy, especially if there are US features suggestive of fetal affection such as intracranial calcifications and hydrocephalus, hydrops fetalis.

**Treatment**

No randomized studies exist on the treatment of *T. gondii* infection in pregnant women and newborn children with congenital toxoplasmosis.

Maternal therapy recommended is spiramycin (3 million units/day). PND is performed by amniocentesis and serial US. If fetal infection is confirmed by PCR, IgM—pyrimethamine (50 mg/day) plus sulfadiazine (2-3 g/day) for 3 weeks alternating with spiramycin (3 million units/day) till delivery are started after parental counseling. Monitoring of mother for potential hematological toxicity of high-dose pyrimethamine should be done, of 35 infants born to mothers with toxoplasmosis acquired during pregnancy, who received spiramycin from diagnosis through labor and two received pyrimethamine and sulfadiazine at birth, infants had IgG antibody titers ranging from 1/1,350 to 1/109,350. All infants initially received pyrimethamine, sulfadiazine and folic acid but in only four cases treatment was continued beyond the 2nd month of life. Transient neutropenia was commonly observed. A follow-up period of 1.2-8.2 years did not reveal any remarkable sequelae. Treatment of infants without substantial neurologic disease at birth with pyrimethamine and sulfadiazine for 1 year results in normal cognitive, neurologic and auditory outcomes for all patients. Treatment of infants who had moderate or severe neurologic at birth resulted in normal neurologic and/or cognitive outcomes for greater than 72% of the patients and none had sensorineural hearing loss. Ninety-one percent of children without substantial neurologic disease and 64% of those with moderate or severe neurologic disease at birth did not develop new eye lesions. Almost all of these outcomes were markedly better than outcomes reported for children who were untreated or treated for 1 month in earlier decades (p < 0.01-0.001).

Review of 26 cohorts—1,438 treated mothers identified by prenatal screening, found weak evidence that treatment started within 3 weeks of seroconversion reduced mother–to–child transmission compared with treatment started after 8 or more weeks [adjusted odds ratio (OR) = 0.48, 95% confidence interval (CI) = 0.28–0.80; (p = 0.05); Systematic Review on Congenital Toxoplasmosis (SYROCOT) Study Group]. In 550 infected live born infants identified by prenatal or neonatal screening, there was no evidence that prenatal treatment significantly reduced the risk of clinical manifestations (adjusted OR for treated vs untreated = 1.11, 95% CI = 0.61–2.02). Increasing gestational age at seroconversion was strongly associated with increased risk of mother–to–child transmission (OR = 1.15, 95% CI = 1.12–1.17) and decreased risk of intracranial lesions (0.91, 0.87–0.95), but not with eye lesions (0.97, 0.93–1.00).

Prospective study of 163 mothers with acute toxoplasma infection before 28 weeks of amenorrhea received antiparasitic treatment with 9 million IU spiramycin orally, 23 also received pyrimethamine and sulfadiazine. All had cordocentesis and regular obstetric US examinations. The 162 live born infants were followed up for 15–71 months. Three fetuses died in utero. 27 of 162 live born infants had proven congenital toxoplasmosis: 10 had one or more clinical signs of congenital toxoplasmosis; five had isolated or multiple intracranial calcifications; seven had peripheral
Fetal tachyarrhythmia may cause fetal hydrops, and lead to fetal morbidity and mortality.

Supraventricular Tachycardia and Atrial Flutter

Supraventricular tachycardia and atrial flutter (AF) have been the most diagnosed.

Treatment

Various treatment modalities have been reported, with no consistent success. The efficacy of antiarrhythmic drug therapy for fetal AF has not been well established. Ectopic (premature atrial/ventricular) beats: Caffeine, sympathomimetic drugs should be avoided. Cases should be followed up weekly for SVT.

Digoxin and sotalol: They may be considered as the drugs of choice for fetal AF. If the fetal AF is resistant to these therapies, a combination of other congenital cardiac diseases or organic abnormalities should be considered. If maternally administered oral digoxin for the treatment of fetal SVT complicated by hydrops fetalis is ineffective secondary to poor transplacental drug transfer, maternal intravenous (MIV) administration of digoxin may be needed, using standard loading and maintenance protocols. MIV digitalis can be converted to oral after fetal stabilization. A case of fetal AF at the gestational age of 25 weeks with atrial rates of 480–520 beats per minute (bpm) and ventricular rates of 200–250 bpm was treated with digoxin then with a combination of digoxin and sotalol. The fetal heartbeat slowed after sotalol treatment but did not return to sinus rhythm. The fetus was delivered vaginally. Neonatal echocardiography showed a small apical ventricular septal defect and small patent ductus arteriosus.

Combination of fetal intramuscular (FIM) digoxin and MIV is described in refractory cases. FIM is administered at a dose of 88 µg/kg q12–24 hours, to a maximum of three injections in the fetal buttock. Direct FIM injection of digoxin combined with transplacental therapy appears to shorten the time to initial conversion of SVT and to sustain sinus rhythm in the fetus with SVT complicated by hydrops fetalis, conversion occurs by 1 week or so.

Amiodarone with digoxin or flecainide: It has been used successfully to convert SVT to sinus rhythm with resolution of hydrops, postnatal electrical cardioversion may be required, with no recurrences in AF after neonatal period.

One large study on management of fetal arrhythmia on the basis of superior vena cava (SVC)/ascending aorta (AA) Doppler flow velocity recordings of irregular rhythms in 307 cases showed that premature atrial and ventricular contractions were easily identified and generally self-limited in time. There was sustained bradycardia (n = 19), four had sinus bradycardia, six presented with blocked atrial bigemism, three showed 2:1 and five had a complete atrioventricular (AV) block. Another fetus that presented with first-degree AV block developed a Luciani-Wenckebach phenomenon 1 week later. Tachyarrhythmia developed in (n = 30). Five types of tachyarrhythmia were observed:

1. **Type I**: Short ventriculoatrial (VA) tachycardia (VA < AV; n = 11). Ten fetuses of this group were considered to have reentrant tachycardia through a fast-conducting AV accessory pathway; all 10 responded to digoxin therapy. The eleventh fetus with short VA tachycardia had atrial ectopic tachycardia with AV node dysfunction was treated successfully with sotalol.

2. **Type II**: Long VA tachycardia (VA > AV; n = 8). The drug of first choice in this group was sotalol.

3. **Type III**: Simultaneous onset of atrial and ventricular contractions: (n = 3). Two responded to amiodarone. The other fetus converted spontaneously to sinus rhythm.

4. **Type IV**: Flutter; (n = 7). Digoxin was prescribed as a first choice associated with sotalol in three cases. Conversion to sinus rhythm was documented in all; however, one hydropic fetus with advanced cardiomyopathy died 1 day after birth.

5. **Type V**: Ventricular tachycardia; (n = 1). The arrhythmia responded well to propranolol and no recurrence was recorded after birth.

Precise prenatal identification of arrhythmia type can be achieved with the SVC/AA Doppler approach. Such information allows for a better management and a rational choice of appropriate antiarrhythmic drug.

Congenital Complete Heart Block

Congenital complete heart block is an uncommon fetal arrhythmia characterized by complete dissociation of the atrial and ventricular contractions, the result of an anatomical anomaly of the conduction pathways, or even the transplacental passage of maternal antibodies causing fetal myocarditis with fibrosis of the conduction tissue, cardiac defects seen in 50% with a mortality rate of 20–30%.

Treatment

Cardiac pacing after premature delivery is associated with high morbidity and mortality, but it may be required in
case of distress and/or deteriorating cardiac function with development of hydrops due to cardiac failure. Vaginal delivery can be safely accomplished in patients with isolated congenital complete heart block, with the use of US and fetal scalp blood sampling to assess fetal well-being during labor and delivery, with postnatal pacemaker implantation if heart rate is still below 50 bpm.30

Prenatal treatment with oral sympathomimetic medication may allow delivery to be delayed until term. In presence of maternal anti-SS-A/Ro Bl Ab, maternal Betamethasone or dexamethasone, 4 mg daily can be useful.

In hydropic fetuses, MIV salbutamol/oral terbutaline raises ventricular rate by 20%. An increase in the fetal ventricular rate and complete resolution of hydrops fetalis occurred in a case of fetal complete heart block diagnosed in a 30-year-old woman when cardiac decompensation was detected at 32 weeks, and she was treated with oral terbutaline after a trial of IV isoproterenol.31 A male infant was delivered by Cesarean section at term, and underwent cardiac pacemaker implantation at 4 days of age with a successful outcome.

**CARDIAC MALFORMATIONS**

Cardiac malformations are common, with major lesions affecting about 3.5 per 1,000 pregnancies; however, only a small proportion of these is likely to benefit from an intrauterine medical intervention. Recent research and clinical developments have included percutaneous valvuloplasty for severe aortic and pulmonary stenosis, perforation of the closed or restrictive interatrial septum and pacing for complete heart block.32 Progress in these endeavors has been variable but overall shows promise for treatment of the human fetus.

**RHEUS ISOIMMUNIZATION**

Fetal death due to anemia (hydrops fetalis) and hemolytic disease of the newborn, secondary to Rhesus (Rh) alloimmunization, is still a major contributor to perinatal morbidity and mortality in India. Preterm delivery and neonatal exchange transfusion are commonly practiced in general, and plasmapheresis has outgrown its usefulness.

**Treatment**

**High-dose maternal intravenous immunoglobulin (IVIg) therapy** blocks Fc (fragment, crystallizable)-mediated antibody transfer across the placenta, blocks Fc receptor-mediated phagocytic function in reticuloendothelial system of mother and fetus, thereby reducing fetal red cell hemolysis. IVIg thus prevents or delays onset of fetal anemia, decreases need for IUT.33

**Fluoroscopic-guided intraperitoneal (IPT) IUT** was the first method of fetal blood transfusion to correct fetal anemia, by the pioneer in fetal therapy—Sir William Liley in 1963. The invention of US and subsequently cord blood sampling has made US-guided fetal blood transfusion a revolution in the management of Rh-isoimmunization, and replaced the more invasive fetoscopic-guided IUT. Planned delivery is done at a center where neonatal exchange transfusion can be performed after pregnancy is carried up to near term with IUTs for the anemic fetus.

**Ultrasound-guided fetal blood transfusion IUT (IVT, IPT):** Intensive monitoring by serial US for fetal anemia, serial middle cerebral artery peak systolic velocities using Doppler US, when necessary invasive testing with techniques such as serial amniocenteses to detect fetal bilirubin by delta-OD (450), and cordocentesis for Hb. If packed cell volume (PCV) is less than 30, or there is fetal hydrops, IUT is carried out through US-directed direct IVT or IPT injection of red cells. Fetal hydrops, mostly associated with late referrals, decreases the chance of survival. To improve the outcome of red cell alloimmunized pregnancies, early diagnosis of fetal anemia and referral to a specialized center are important, enabling the start of treatment IUT before hydrops develops.

Of 18 Rh-negative pregnant women presenting during a 7-year period, managed with serial intrauterine IVTs with the goal of delivery by Cesarean section beyond 33 weeks of gestation, 11 were mildly and seven severely hydropic fetuses.34 All fetuses with mild hydrops and five of the seven with severe hydrops were delivered alive after 32 weeks of gestation in a good condition. Two fetuses both with severe hydrops died in utero, at 28 weeks of gestation. Intrauterine reversal of hydrops occurred in 90.9% of fetuses with mild hydrops and in 57.1% of severely hydropic fetuses. The survival rate for the hydropic fetuses was 89.9% and prognosis was associated with the severity of fetal hydrops.

In prospective cohort study of 99 Rh-isoimmunized pregnancies referred to All India Institute of Medical Sciences (AIIMS) conducted over the last 5 years, 43 (25 hydrops fetalis and 18 non-hydropic fetuses) required 135 intrauterine blood transfusions, while the rest 56 pregnancies were managed conservatively.35 In the 43 cases who required transfusion, IUT was done starting from 16 weeks (IPT), 21 weeks (IVT) of gestation by the IPT/IVT routes. Pre-transfusion Hb ranged from 3 g% to 8 g%. Amount of blood transfused varied from 10 mL to greater than 110 mL depending on the period of gestation and degree of fetal anemia. Number of transfusions per pregnancy was 1–7, at intervals of 1–4 weeks, till delivery at 28–36 weeks of gestation. Overall survival rate was 86%. Survival of hydropic fetuses (72%) was significantly different from those without hydrops (89%); and in those receiving IUT (83.3%) versus without IUT (94%). Low survival rates were especially found in hydropic fetuses with the first transfusion at gestational ages of 20 weeks or less and in those with severe hydrops.

Over an 8-year period, 221 in utero transfusions were performed for Rh disease in 66 pregnancies. 86% had severe fetal anemia caused by anti-D, 10.6% by anti-Kell and 3.4% by anti-c.36 The median gestation at initial IUT was
25 weeks [interquartile range (IQR): 23–29 weeks]. A median number of three IUTs were performed in each fetus, with a median Hb at first fasting blood sugar (FBS) of 7.3 g% (IQR 4.6–8.8 g%) [73% ≤ 5 standard deviation (SD) and 27% ≤ 2 SD].

Of the total IVTs, 170 were performed via the intrahepatic vein (IHV) route (71.7%), 33 via cordocentesis (13.9%) and one by intracardiac puncture (0.5%). There were “transient” bradycardias complicating 4.1% of all transfusions and amniorrhexis following 1.4%. 92% of babies were live born at a median gestation of 34 weeks (range: 21–38). There was no significant difference in IVT complication rate when the procedure was performed via the IHV (7.6%) as compared to cord root puncture (3.0%).

FETAL SURGICAL THERAPY

Fetal structural abnormalities have a wide spectrum of clinical severity and prognosis. Detailed US should be done for other associated abnormalities or syndromes. Fetal status, prognosis has to be assessed in consultation with pediatric surgeon, neonatologist and geneticist. Parents have to be counseled on risk, prognosis, interventions during pregnancy or after birth (infancy and childhood, e.g. renal transplant), cost, hospital stay. If the structural defect is suggestive of a chromosomal abnormality, a fetal karyotype is performed by amniotic fluid or cord blood sampling. A lethal anomaly such as bilateral renal agenesis, anencephaly is best managed by TOP. An anomaly detected late, with mild organ damage such as mild ventriculomegaly, hydronephrosis may be left alone and the newborn managed after birth. If continuation of the pregnancy is desired in a case with fetal structural defect which could cause grave organ damage, morbidity or mortality if left alone in the expectation of treatment after birth, the option of therapeutic intervention during fetal life in utero fetal surgery is now possible for some conditions. In the 1990s, the merger of fetoscopy and advanced videoendoscopic surgery formed the basis for endoscopic fetal surgery. In India, very few centers such as the AIIMS, New Delhi, are involved in research and patient care in this exciting, rapidly advancing field.

Pertinent aspect of some defects and corrective fetal surgical procedures are described in Table 1.

URINARY TRACT OBSTRUCTIVE DEFECTS

Lower urinary tract obstruction (LUTO) is commonly meant when discussing obstructive uropathy. Three serial bladder taps—“vesicocentesis” performed over the course of 3–4 days is most predictive of identifying underlying renal injury.

Fetal Vesicocentesis

Under continuous US guidance with color Doppler visualization to prevent inadvertent umbilical vessel injury, a 22/23 gauge needle is inserted into the fetal bladder. The bladder is completely emptied of urine by aspiration with 20-mL syringe or continuous rapid suction, while constantly maintaining the needle tip placement within the cavity of the shrinking bladder. The urine is sent for required analysis. Urine obtained at the initial bladder drainage represents old urine from within the fetal bladder. Urine from the second drainage represents urine that has collected in the bladder from the upper collecting systems. The third tap is fresh urine and is the most predictive of underlying renal function. In some cases,
however, a fourth or fifth tap is needed to determine renal status. The urine is analyzed for electrolyte and protein values as a reflection of the level and severity of damage to the fetal kidneys. Fetuses that demonstrate progressive hypotonicity on sequential urine samples and have final values which fall below recommended thresholds have been shown to benefit from in utero intervention. Fetal urine evaluation parameters showing good prognosis are:41

- Sodium ≤ 100 mg/dL
- Osmolality ≤ 200 mOsm/L
- Chloride ≤ 90 mg/dL
- Calcium ≤ 8 mg/dL
- Total protein ≤ 20 mg/dL
- β-2 microglobulin ≤ 6 mg/L

A fetal echocardiogram should also be performed to rule out congenital heart defects that occur in increased frequency in these cases. An ultrafast fetal magnetic resonance imaging (MRI) can be useful in evaluating the kidneys, collecting system and bladder in complex cases.

**Percutaneous Vesicoamniotic Shunt**

This is performed if kidney functions are normal, the karyotype is normal and there are no major malformations. It can be performed under local, regional or general anesthesia, usually local.42

The location and position of the placenta and fetus are identified on US to avoid passing through the placenta. Since most of these fetuses have oligohydramnios, amnioinfusion may be carried out if there is severe oligoamnios to facilitate catheter placement using warmed Ringer’s lactate solution; it is helpful in the placement of proximal part of shunt into the uterine cavity and not in the myometrium. The ideal fetal site of entry is below the umbilicus, avoiding vessels as seen by color Doppler. Fetus is first given analgesia (0.2 µg/kg pancuronium, 10 µg/kg/fentanyl). The maternal skin is anesthetized with 1% lignocaine, a small 3–5 mm stab wound made and shunt trocar carefully introduced into the amniotic space and then into the fetal bladder using sharp, shift movement and positioned centrally. Urine sample is aspirated, sent for culture and renal function. The double pigtail “Rodeck” or “Harrison” shunt catheter is now threaded into the trocar sheath prior to insertion of internal stylet wire. Using push rods, the proximal segment of the catheter is pushed into the fetal bladder while the distal end positioned in the amniotic space drains out the urine. US at 24–48 hours and then weekly for 4–6 weeks needs to be done to confirm proper catheter placement and function, amniotic fluid volume and progressive resolution of bilateral hydronephrosis. With shunt therapy, as the bladder shrinks, dislocation and malfunction of the shunt may occur in 60% cases due to pull from skin into the fetal abdomen or shunt being pulled out of the fetus into the amniotic cavity.

**Percutaneous Fetal Cystoscopy**

Techniques to evaluate the inside of the fetal bladder and proximal urethra (in utero microcystourethroscopy), identify the source of obstruction and surgically destroy it prenatally are being developed.44 This would eliminate need for temporary shunts with their inherent physical limitations, and it would allow more normal bladder and urinary tract development during fetal life.44

**Fetal Endoscopic Ablation of Ureteral Valve**

A 3 mm/3.9 mm trocar with 2.7 mm/3.3 mm operating endoscope is used. The fetal bladder is entered as in shunt procedure, and ablation of ureteral valve or ureterocele wall lysis is done using contact yttrium-aluminum-garnet (YAG) laser.

**Endoscopic Fetal Cystotomy (EFC): Fetal Hydrolaparoscopy (FHL) Ablation of PUV**

Similar to adult laparoscopy, access into the fetal peritoneal cavity by the endoscope is achieved, the bladder identified, dome incised using 20 W laser, and a 3.3 mm endoscope inserted inside the bladder and posterior urethral valves (PUV) ablated.

**Retrograde Urethral Catheterization (RUC)**

Fetal endoscope is inserted into the amniotic cavity near fetal penis. Foreskin is grasped with 1 mm forceps. A 2 mm monopolar electrode is passed into the urethra under laser.

**Prognosis**

Antenatal treatment of obstructive uropathy, although widely performed, remains controversial. In one large study, 58 patients were followed up from 6 months to 6 years and 6 months (mean 3.9 years).45 Group I included 12 patients who had vesicoamniotic shunt placement, and were confirmed postnatally to have PUV. Four fetuses died (33.3%); three out of the eight living had perinatal complications. Of the eight living neonates, three (37.5%) underwent valve ablation and five (62.5%) underwent urinary diversion (three vesicostomies and two cutaneous ureterostomies). Renal function returned to normal in only four (50%). Radiological abnormalities (hydronephrosis and/or reflux) resolved in three (37.5%), was downgraded in one (12.5%) and persisted in four cases (50%). Group II included 46 patients who were treated postnatally. Thirty-five (76%) underwent primary valve ablation, while 11 (24%) underwent urinary diversion (seven vesicostomies, four cutaneous ureterostomy and one
pyelostomy). Renal function returned to normal in all babies who underwent valve ablation, except in three, while renal function returned to normal in only three of 11 patients who underwent urinary diversion. Radiological hydronephrosis and/or reflux resolved in 28 patients (60.9%), was downgraded in six patients (13%) and persisted in 12 patients (26.1%).

Clinical outcomes in 20 pregnancies with a singleton male fetus, oligo/anhydramnios and LUTO studied, 1-year survival was 91%. Two neonatal deaths occurred from pulmonary hypoplasia. Mean days from shunting to delivery were 84.4, and mean birthweight was 2,574 g. Prenatal urinary prognosis was good in 13, borderline in two and poor in three of the survivors. Mean age at follow-up was 5.83 years. PUVs were confirmed in seven males, urethral atresia in four and prune belly syndrome in seven. Eight children had acceptable renal function, four had mild insufficiency, and six required dialysis and eventual renal transplant. Eleven children had normal bladder function with spontaneous voiding, six required catheterization and one child still had a vesicostomy. Although one-third of the surviving babies required dialysis and transplantation, the majority have acceptable renal and bladder function, and reported satisfactory quality of life. Thirty-three percent developed renal failure but did well after renal transplant.

Thus, antenatal vesicoamniotic shunt placement appears to make no difference to the outcome and long-term results of patients with PUV and debate about its efficacy on renal outcome remains. Primary valve ablation is emerging as the keystone of treatment for patients with PUV that might achieve the primary goal of nephron preservation. The lowest creatinine concentration in the 1st year of life is the most appropriate predictor of future renal function.

### LUNG DEFECTS

#### Congenital Cystic Adenomatoid Malformations

Congenital cystic adenomatoid malformation (CCAM) of the lung is a nonfunctioning benign lung tumor, hamartomatous or dysplastic in origin. They may be: macrocystic—usually a single, 2–10 cm cyst within lungs, and microcystic—appearing as solid, echogenic mass. Hydrops fetalis and polyhydramnios warrant fetal intervention. Treatment by means of decompression can improve substantially the clinical results in these patients. Antenatal evaluation using US, amniocentesis, PUBS and cardiac echo should be carried out to look for the presence of other fetal anomalies and fetal prognostic markers. If fetal hydrops is not present, the mother should be followed by serial US scans and arrangements made for appropriate postnatal care. An elective postnatal resection of lung mass at 4 weeks of age can be carried out. If the fetus has hydrops, or hydrops develops during follow-up, then management depends on the gestational age. For fetuses more than 32 weeks, delivery of the fetus and resection of the lesion ex utero in a center with extracorporeal membrane oxygenation (ECMO) facilities is appropriate.

#### Fetal Surgery

For fetuses that develop hydrops before 32 weeks of gestation, treatment options are:

- **Microcystic CCAM**
  - Posterolateral thoracotomy with resection of involved lobe
  - Percutaneous intrauterine laser therapy

- **Macroscopic CCAM**: Thoracoamniotic shunt placement: It carries a 70% success rate. Effect of prenatal pulmonary drainage (shunt, surgery or drainage) on perinatal survival was compared with no treatment, in fetuses with ultrasonic evidence of lung pathology, in 16 controlled observational studies involving 608 fetuses which showed that pulmonary drainage did not improve perinatal survival in cystic lung lesions compared with no drainage (OR = 0.56, 95% CI = 0.32–0.97, p = 0.04) overall. However, there was a marked improvement with this therapy in a subgroup of fetuses with fetal hydrops fetalis (OR = 19.28, 95% CI = 3.67–101.27, p = 0.0005) but not in the subgroup uncomplicated by fetal hydrops fetalis (OR = 0.04, 95% CI = 0.01–0.32, p = 0.002).

#### Bronchopulmonary Sequestration

Bronchopulmonary sequestrations (BPS) are intralobar and extralobar lung masses of benign pulmonary tissue without tracheobronchial communication. Prenatal identification of feeding vessel establishes the diagnosis of pulmonary sequestration allowing its differentiation from CCAM. Fetal extralobar pulmonary sequestration (EPS) is sometimes complicated by massive pleural effusion (PE) leading to fetal hydrops.

#### Fetal Surgery

Pleuro-amniotic shunting should be considered as a treatment option for fetal hydrothorax and hydrops associated with BPS. Procedure is same as vesicoamniotic shunt. Antenatally diagnosed “cystic lung disease” have an excellent prognosis in the absence of signs of hydrops.

#### Pleural Effusion

Fetal PEs may lead to lung compression and hypoplasia, and could be due to chylothorax.

#### Fetal Surgery

*Thoracoamniotic shunt* PE and skin edema on the thorax decreased significantly after shunt placement compared to
Twin-Twin Transfusion Syndrome

Twin-twin transfusion syndrome complicates approximately one in five of all monochorionic, diamniotic twin pregnancies. If of early onset and untreated, severe TTTS is associated with a dismal prognosis with perinatal mortality rates exceeding 90%. Left untreated, severe TTTS presenting in the early second trimester of pregnancy is often associated with significant maternal morbidity and almost universal perinatal loss.

Fetal Surgery

Selective Fetoscopic Laser Coagulation

Selective fetoscopic laser coagulation of vascular anastomoses on the placental surface in severe midtrimester twin-twin transfusion is a potentially corrective and effective, minimally invasive procedure. Endoscopic coagulation of the vascular anastomoses responsible for fetofetal transfusion is done with a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser.54 With the use of local anesthesia and continuous US visualization, a rigid fetoscope 2 mm in diameter, housed in a 2.7 mm cannula, is introduced transabdominally into the amniotic cavity of the recipient twin. A systematic search is made for all vessels approaching or crossing the membrane between the twins, and these are coagulated with an Nd:YAG laser by means of a fiber in the side arm of the cannula.

Perinatal survival is significantly higher when treatment is performed in the early Quintero stages (95% in stage I, 76% in stage II, 70% in stage III, 50% in stage IV) (p = 0.02). Treatment with laser coagulation in 100 consecutive pregnancies with severe second trimester TTTS at median gestational age of 20 weeks (range: 16–26) resulted in mean gestational age of 33 weeks at delivery (range: 18–40). Perinatal survival rate of 70% (139/200), with at least one survivor at the age of 4 weeks in 81% of pregnancies was successfully prevented by OK-432.53

Multiple Pregnancies

Serial Amnioreduction

Removal of excessive amounts of amniotic fluid through serial amniocenteses [amnioreduction (AR)] has been the mainstay of therapy. Under US guidance, a needle is inserted into the amniotic cavity and amniotic fluid drained using suction drainage. A 5 year multicenter, prospective, randomized controlled trial of AR versus selective fetoscopic laser photocoagulation (SFLP) for the treatment of severe TTTS showed that there was no statistically significant difference in 30-day postnatal survival between SFLP or AR treatment for donors at 55% (11 of 20) versus 55% (11 of 20).57 Overall survival (newborns divided by the number of fetuses treated) was not statistically significant for AR at 60% (24 of 40) versus SFLP 45% (18 of 40). The outcome of the trial did not conclusively determine whether AR or SFLP is a superior treatment modality. TTTS cardiomyopathy appears to be an important factor in recipient survival in TTTS.

Septostomy

A single puncture under US guidance is used for the intentional perforation of the intervening twin membrane (septostomy). Of 73 women with TTTS before 24 weeks gestation randomly assigned to serial AR or septostomy, the rate of survival of at least one infant was similar in the AR group compared to the septostomy group [78% vs 80% of pregnancies, respectively; relative risk (RR) = 0.94, 95% CI = 0.55–1.61; p = 0.82]. Patient undergoing septostomy were more likely to require a single procedure for treatment (64% vs 46%; p = 0.04), and offers the advantage of often requiring a single procedure compared to serial AR in the treatment of severe TTTS.58

Umbilical Cord Ligation/Occlusion

Twin Reversed Arterial Perfusion

Twin reversed arterial perfusion (TRAP) occurs only in the setting of a monochorionic pregnancy, and complicates approximately 1% of monochorionic twin gestations, with an incidence of 1 in 35,000 births. Due to the abnormal circulation and the increased demand that the abnormal twin places on the heart of the pump twin, cardiac failure is of primary concern in TRAP sequence. If heart failure is left untreated, the pump twin dies in 50–75% of cases. This is especially true when the acardiac/acephalic twin is greater than 50% of the size of the pump twin by calculated estimated weight.
**Fetal Surgery**

**Fetoscopic Laser Coagulation**

Fetoscopic laser coagulation of placental vascular anastomoses or the umbilical cord of the acardiac twin is an effective treatment of TRAP sequence. This procedure is performed under continuous US guidance and involves the placement of a 3 mm diameter trocar needle into the amniotic space of the pregnant uterus. A 2-mm fetoscope (operative telescope) is then passed into the amniotic space in the umbilical cord and the abnormal fetus examined. Once an adequate site for cauterization is identified, the fetoscope is removed and a 2.7 mm bipolar instrument is introduced into the amniotic space. With US assistance it is guided to the chosen segment of umbilical cord. The umbilical cord is grasped by the bipolar instrument and cauterized, which closes off the blood vessels and blood flow to the abnormal fetus. The umbilical cord is released and again grasped 2–3 cm from the original site and cauterized again as a safety precaution measure. The bipolar instrument is removed and the fetoscope is again placed into the amniotic space and the two surgical sites are carefully examined.

In a prospective multicenter study, percutaneous fetoscopic laser coagulation of placental anastomoses (n = 18) or the umbilical cord of the acardiac twin (n = 42) was performed in 60 consecutive pregnancies at a median gestational age of 18.3 years (range: 14.3–24.7) weeks under local or locoregional anesthesia. Vascular coagulation with arrest of blood flow was achieved in 82% (49/60) of cases by laser alone and in a further 15% (9/60) by laser coagulation in combination with bipolar forceps, survival rate of 80%, and 67% of pregnancies with surviving pump twins going beyond 36 weeks gestation without further complications. Median interval between the procedure and delivery was 18.2 (range: 1.1–25.7) weeks. Median birthweight was 2,720 g (range: 540–3,840 g). Preterm premature rupture of membranes before 34 weeks gestation occurred in 18% (11/60) at a median of 62 (range: 1–102) days after the procedure, only two (3%) women delivered within 28 days of the procedure.

**CONGENITAL DIAPHRAGMATIC HERNIA**

This condition occurs in about one in every 2,500 livebirths. Absence of the diaphragm may occur on the left side or both sides, but the absence on the left side is most common. Correction of congenital diaphragmatic hernia (CDH) in utero has been very dramatic and many lessons in fetal therapy have been learnt.

**Fetal Surgery**

**Fetal Endoscopic Tracheal Occlusion (Clip/Balloon)**

Fetal tracheal occlusion (TO) was developed in an attempt to enhance prenatal lung growth and improve survival in fetuses with severe CDH. This procedure is performed at 23–27 weeks of gestation. Preoperative betamethasone is given to mother for fetal lung compliance. Under general anesthesia through low transverse maternal laparotomy, a 5-mm trocar is inserted into the uterus, and a 4-mm perfusion hysteroscope is guided through the fetal vocal cords under fetoscopic and US guidance. A detachable silicone balloon (target therapeutics) is placed in the fetal trachea midway between the carina and vocal cords, and inflated with iso-osmotic contrast material so as to fill the fetal trachea (0.5 mm diameter) and for at least 2 cm length. Pregnancy is continued.

**Ex Utero Intrapartum Therapy**

At delivery, ex utero intrapartum therapy (EXIT) procedure to ECMO is done. ECMO is a temporary heart/lung bypass machine that some babies with CDH need to help them survive the first a few days or weeks following birth. The EXIT procedure has been designed to provide time to secure an airway while the baby is still attached to the umbilical cord and to preserve uteroplacental gas exchange. The procedure was originally described for delivery of fetuses with diaphragmatic hernia who had undergone in utero tracheal clip application to induce prenatal lung growth. At Cesarean section, a special uterine stapling device is used to open the uterus to prevent bleeding. General anesthesia is used to preserve uteroplacental blood flow, which allows time to perform procedures such as direct laryngoscopy, bronchoscopy, tracheostomy, surfactant administration, cyst decompression and tumor resection, some or all of which may be required to secure the airway and provide adequate ventilation.

The largest reported experience using EXIT to ECMO in the management of severe CDH showed that the procedure is associated with favorable survival rates and acceptable pulmonary morbidity in fetuses expected to have a poor prognosis under conventional management. Of 14 fetuses with severe CDH (liver herniation and a lung/head ratio less than 1.4, percentage of predicted lung volume less than 15, and/or congenital heart disease) that underwent EXIT with a trial of ventilation, fetuses with poor preductal oxygen saturations despite mechanical ventilation received ECMO before their delivery. Three babies passed the ventilation trial and survived, but two of them required ECMO within 48 hours. The remaining 11 fetuses received ECMO before their delivery. Overall survival after EXIT-to-ECMO was 64%. At 1-year follow-up, all survivors had weaned off supplemental oxygen, but 57% required diuretics and/or bronchodilators.

**Potential Risks to the EXIT Procedure**

Bleeding from uterine atony—with expert management and stapling device, the average intraoperative maternal blood loss of around 930 mL, is well within the accepted range for traditional Cesarean section.
Fetal Therapy: Medical and Surgical

A randomized, controlled clinical trial in 24 fetuses with severe left CDH (liver herniated into the thorax and low lung-to-head ratio) to compare survival after endoscopic fetal TO versus standard perinatal care (control) and follow-up of the 16 survivors (9 control, 7 TO) to compare neurodevelopmental, respiratory, surgical, growth, and nutritional outcomes, showed that 1-year and 2-year old, infants with TO were significantly more premature at birth (control vs TO, 37.4 ± 1.0 vs 31.1 ± 1.7 weeks; p < 0.01). There was considerable catch-up growth by age 2 years (growth failure: control vs TO, 22% vs 33%; p = 0.19). There were no differences in other growth parameters. There were also no differences in neurodevelopmental outcome at 1 year and 2 years. Supplemental oxygen at hospital discharge was a significant predictor of worse neurodevelopmental outcome at 1-year and 2-year old (p = 0.05 and p = 0.02, respectively). Fetuses with severe CDH, carries significant risk of chronic morbidity. Factors found to predict death of live-born infants include right-sided hernia, major air leak, earlier gestational age at birth, lower birthweight and lower APGAR scores at 1 minute and 5 minutes.

Wide variations in survival rates are reported throughout literature, reflecting the influence of case selection bias, as well as variable referral policies and management practices. Overall mortality rate for this condition remains high, despite increased prenatal detection, transfer to tertiary institutions for delivery, and advances in neonatal care.

**FETAL TUMORS**

Giant neck masses, such as *cervical teratoma* and *lymphangioma*, can grow to such large proportions that the fetal airway becomes distorted and obstructed. In a small number of patients with cervical teratomas, the mass effect pulls the lungs into the apex of the chest and results in pulmonary hypoplasia.

In addition to obstructing the airway, these giant neck masses can compress the esophagus, resulting in polyhydramnios, which can lead to uterine irritability and preterm labor. Unsuspected obstructive fetal neck masses often prove fatal because of an inability to secure an airway and ventilate the neonate, which results in hypoxia and acidosis. If the delay is longer than 5 minutes, anoxic brain injury may occur. This complication is all the more tragic because most of these children have an isolated anomaly and do well after postnatal resection.

**Treatment**

If the neck mass is small and does not compromise the airway, close US surveillance is warranted to follow the growth of the mass. Polyhydramnios may necessitate amniotic fluid removal in some instance. If polyhydramnios persists and the mass continues to grow, the EXIT procedure is the treatment option of choice.

**SACROCOCCYGEAL TERATOMA**

Sacrococcygeal teratoma (SCT) is the most common tumor of the newborn, occurs in 1 out of every 35,000–40,000 livebirths. They may be cystic, solid or mixed in its sonographic appearance. The heterogeneous appearance of the mass may be due to mixed areas of tumor necrosis, cystic degeneration, hemorrhage or calcification. Most SCTs diagnosed in neonates are not likely to be malignant and the prognosis tends to be good after resection. SCT associated with fetal hydrops can be rapidly progressive and fatal in utero or can lead to polyhydramnios and premature delivery. The high-output cardiac failure is related to “vascular steal” from the high blood flow through the tumor. Fetuses that develop hydrops before 32 weeks, need to be referred to tertiary care center for fetal surgery factor, for either resection, laser vessel ablation, alcohol sclerosis, or cyst drainage.

**Open Fetal Surgery**

Open fetal surgery has been performed in hydropic fetuses or even before hydrops develops. One study of 27/41 SCTs managed antenatally, six underwent TOP, 12 underwent fetal intervention (laser vessel ablation: 4, alcohol sclerosis: 3, cyst drainage: 2, amniodrainage: 2, vesicoamniotic shunt: 1) for fetal hydrops. Of these, three died in utero, nine born alive, median gestational age, 33 weeks (27–37 weeks) but three more died in the neonatal period and six (50%) survived long-term.

Without intervention, 17 infants were born alive at median 38 weeks (26–40 weeks), 16 had excision surgery at median 2 days (1–16 days) with no recurrences on follow-up till median 39 months (8–86 months). Thus, overall survival was 77%, in utero intervention requirement being poor prognostic factor.

Fetal hydrops and placenomegaly may also jeopardize maternal health through the “maternal mirror” syndrome in which the mother’s condition mirrors that of the sick fetus.

**RECENT ADVANCES**

**Hydrocephalus: Neural Tube Defects**

*Hydrocephalus*: It is one of the most common congenital anomalies affecting the nervous system, occurring with an incidence of 0.3–2.5 per 1,000 livebirths. PND is a challenge for the team counseling parents regarding a prognosis for the fetus. True fetal hydrocephalus has a variety of causes: “aqueductal stenosis”,—blockage of cerebrospinal fluid (CSF) passage through the aqueduct of Sylvius; Chiari II malformation syndrome is characterized by myelomeningocele and posterior fossa abnormalities; Dandy-Walker malformation; X-linked recessive hydrocephalus (Bickers-Adam syndrome) characterized by aqueductal stenosis, severe mental retardation. Hydrocephalus may also
be present in a number of major and minor chromosomal aberrations affecting chromosome 8, 9, 13, 15, 18 or 21.

The fetus is followed with serial USs, and if the ventriculomegaly is mild and stable, the fetus is carried to term. Those with mild isolated ventriculomegaly of less than 12 mm have an excellent prognosis. Spontaneous resolution of mild-to-moderate hydrocephalus has been reported in some cases.

A small group of fetuses will undergo rapidly progressive ventricular enlargement, those cases before 28 weeks may have irreversible damage by 32 weeks, with significant adverse outcome. Hence, consideration should be given for early delivery and early shunting, but increased morbidity and mortality data related to prematurity and an increased risk of shunt infection argue against delivery and shunting before 32 weeks. The overall shunt infection rate is 3–10%, but may be as high as 20% in preterm infants. A Cesarean section is preferred, followed by immediate shunt insertion to eliminate vaginal and intensive care unit (ICU) flora exposure and colonization.

Progressive ventricular dilatation greater than 1.5 cm can be offered open surgery in utero, but (Denver) shunts have not been very useful as they got dislodged or obstructed, with poor outcome.67 The International Fetal Medicine and Surgery Society in 1985 agreed to a moratorium on the procedure, so shunting may be considered only in the context of a clinical trial and in a center with extensive experience in fetal surgery.

Open Spina Bifida

This remains a major source of disability despite an overall decrease in incidence. It is estimated that approximately 400 fetal operations have now been performed for myelomeningocele worldwide.68 Despite this large experience, the technique remains of unproven benefit. Preliminary results suggest that fetal surgery results in reversal of hindbrain herniation (the Chiari II malformation), a decrease in shunt-dependent hydrocephalus, and possibly improvement in leg function, but these findings might be explained by selection bias and changing management indications. A randomized prospective trial [the Management of Myelomeningocele Study (MOMS) trial] is currently being conducted by three centers in the United States, and is estimated to be completed in 2009.

FETAL GENE THERAPY

Gene therapy uses the intracellular delivery of genetic material for the treatment of disease. Fetal gene therapy would give another choice following PND of inherited disease, where TOP or acceptance of a treated/affected child is currently the only options. Application of this therapy in the fetus must be safe, reliable and cost-effective. Recent developments in the understanding of genetic disease, vector design and minimally invasive delivery techniques have brought fetal gene therapy closer to clinical practice.

Proof of principle for the hypothesis of fetal gene therapy has been provided during the last 2 years in Mouse Models for Crigler-Najjar disease, Leber’s congenital amaurosis, Pompe’s disease and hemophilia B showing long-term postnatal therapeutic effects and tolerance of the transgenic protein after in utero gene delivery. A wide range of diseases—including cancer, vascular and neurodegenerative disorders and inherited genetic diseases are being considered as targets for this therapy in adults.

Fetal application might prove better than application in the adult for treatment, or even prevention of early-onset genetic disorders such as cystic fibrosis and Duchenne’s muscular dystrophy, because gene transfer to the developing fetus targets rapidly expanding populations of stem cells, which are inaccessible after birth, and use of integrating vector systems results in permanent gene transfer.69

In animal models of congenital disease such as hemophilia, studies show that the functionally immature fetal immune system does not respond to the product of the introduced gene, and therefore immune tolerance can be induced, treatment could be repeated after birth, if that was necessary. However, recently it has also been observed that there is a high incidence of liver tumors after in utero application of an early form of third-generation equine infectious anemia virus vectors with SIN configuration.

In Utero Hematopoietic Cell Transplantation

Goal of in utero hematopoietic cell transplantation (IUHCT) is to achieve therapeutic levels of chimerism, but it typically achieves low-level mixed hematopoietic chimerism.

Prenatal adoptive immunotherapeutic strategies may achieve complete hematopoietic engraftment across full major histocompatibility complex (MHC) barriers when combined with IUHCT, as was seen in a study of 15 fetal mice that were transplanted with a mixture of C57BL/6 (B6) T-cell-depleted bone marrow (TCDBM) cells and splenocytes from B6 mice presensitized to BALB/C alloantigen.70

The splenocytes were preincubated in L-leucyl-L-leucine methyl ester (LLME), to minimize graft versus host disease (GVHD). Full donor hematopoietic chimerism following a single prenatal transplant was achieved in seven transplanted animals. Fully chimeric animals were healthy, without evidence of GVHD, and maintained their engraftment for the duration of the study (48 weeks). Strategies with greater hematopoietic specificity must be developed prior to consideration of clinical application.

CONCLUSION

Fetal Medical and Surgical Therapy is the exciting new field of expertise for limited but expanding indications, being practiced in few, select centers throughout the world. In India,
it is still in its infancy. Slowly, progress is being achieved and there is wide potential for further development and research, though many obstacles need to be overcome.

SECTION 4

Intrapartum Management
INTRODUCTION
Induction of labor is the nonspontaneous initiation of uterine contraction that results in progressive dilatation and effacement of cervix with descent of the presenting part. It is the initiation of labor by artificial means.

Initiation of labor is usually carried out when continuation of pregnancy endangers the life or well-being of the mother or her unborn child. In current obstetrics practice, induction is usually performed for medical indications, however, sometimes it is performed for patient’s or care provider’s convenience. Despite the safety of induction, a liberal induction policy leads to an increase in operative deliveries creating potential risks for the mother and child.

INCIDENCE OF INDUCTION OF LABOR
Induction rates vary greatly between different countries, population groups and hospitals. National Center for Health Statistics reported that the rate of labor induction increased from 90 per 1000 live births in 1989 to 184 per 1000 live births in 1997.

In 1980, Pearson and Andrews reported induction rate of 4% whilst McNaughton reported it to be 40% in leading institutions of the UK.

Tipton and Lewis (1975) reported the figure to be as high as 55% in nonteaching institutions.

The incidence of induction has increased because of better antepartum and intrapartum surveillance, increased safety of induction, better pharmacological agents for induction and improved neonatal intensive care.

INDICATIONS FOR INDUCTION OF LABOR
The obstetrician who is conducting induction of labor must take into consideration one issue above all others—a detailed risk benefit analysis must indicate that the mother and her fetus are more likely to benefit from than be harmed by the artificial initiation of labor.

For maternal indication or interest, i.e. when continuation of pregnancy endangers mother’s life, induction may be carried out at any stage of pregnancy. However, if it is done for the fetal interests, it is carried out only when fetus is salvageable and safe outside the uterus than inside.

Maternal Indications
- Severe preeclampsia/hypertensive disorders
- Eclampsia
- Intrauterine fetal death
- Accidental hemorrhage
- Premature rupture of membranes (PROM)
- Chorioamnionitis.

Fetal Indications
- Prolonged pregnancy or postdatism
- Fetus with congenital malformations
- Gestational diabetes
- Unexplained intrauterine death in the previous pregnancy
- Maternal hypertensive disorders
- Previous bad obstetric history
• Intrauterine growth restriction
• Various tests for fetal well-being indicating fetal jeopardy, e.g. fetal kick count
  - Nonstress test (NST)
  - Visual acoustic stimulation test (VAST)
  - Color Doppler flow studies
  - Biophysical profile score (BPS)
• Rh-isoimmunization.

### ROLE OF CESAREAN SECTION

Whenever termination of pregnancy is indicated and if vaginal delivery is not possible or contraindicated it would be wiser to do cesarean section, e.g. in case of malpresentation, cephalopelvic disproportion, placenta previa, severe placental insufficiency, uninducible cervix where ripening may not be possible.

### FACTORS INFLUENCING THE OUTCOME OF INDUCED LABOR

The aim of induction of labor is to achieve a safe vaginal delivery for the fetus without causing any harm to the mother. Failed induction of labor may be associated with a poorer neonatal outcome and/or long labor with physical and emotional disturbances for the mother. Failed induction has been defined by Duff et al. (1984) as the failure to enter the active phase of labor after 12 hours of regular contractions.

Failed induction is diagnosed when a woman who was induced did not deliver vaginally in the absence of fetal distress, with acute events like abruption or prolapsed cord and/or failure to progress due to cephalopelvic disproportion and if the patient has not entered the active phase of labor despite adequate management for 12 hours.

The success of any method of induction depends largely on the parity and the state of the cervix at the beginning of induction. The process of prelabor cervical softening, shortening and eventual dilatation is a part of a continuum which culminates in spontaneous labor. The success of any method of induction in particular circumstances depends largely on the point in this continuum at which the efforts of induction start.

Cesarean section rate for failed induction of labor according to parity and cervical score is shown in Table 1.

### METHODS OF CESAREAN PRIMING

During last several years the use of different methods for cervical priming have become popular. During the process of cervical ripening, important structural and chemical changes take place and create a cervix that requires less uterine work to achieve cervical dilatation. A method used for cervical ripening might act as a method to induce labor.

#### Pharmacological Methods of Cervical Ripening

**Prostaglandins**

Prostaglandin E2 (PGE2) has been used through various routes: (a) oral, (b) intracervical and (c) vaginal.

- Oral PGE2 0.5 mg tablet 1 hourly for 4-8 tablets
- Intracervical instillation of PGE2 0.5 mg gel is done taking care that instillation is done below the level of internal os. Many a times besides ripening the cervix, uterine activity is also initiated. In case of poor response, repeat instillation may be done after 12–24 hours. During this period, fetal health surveillance (FHS) should be monitored.

Rafiqul Islam, Sritanu Bhattacharya and Bejoy Lakshmi Goswami (2001) in their prospective study to evaluate efficacy of intracervical PGE2 gel, showed that the mean initial Bishop score of 2.7 improved to 5.6 after 6 hours and to 9.6 after 12 hours in 84% cases. Only 16% cases required re-instillation of PGE2 gel. The success rate in terms of vaginal delivery was 75.6% with initial Bishop score of 1 to 2 and 88% in cases with a score of 3 to 4.

**Oxytocin**

Before introduction of prostaglandins, intravenous (IV)-infusion of oxytocin or buccal oxytocin was the usual method of ripening the cervix. However, IV-oxytocin is a laborious approach necessitating constant monitoring and was requiring 8–15 hours session, spaced over a number of days. Controlled studies have shown it to be a less satisfactory method than local PG application.

### METHODS OF INDUCTION OF LABOR

Historically, a wide variety of mechanical and chemical methods, some of them even bizarre have been used for inducing labor.

Modern obstetrics practice however uses only two broad approaches to induction of labor, namely amniotomy and the use of oxytocic agents. A third method which is widely used, but rarely a formal method of induction is sweeping or stripping of the membranes.

#### Sweeping or Stripping of Membranes

Sweeping or stripping of membranes from the lower uterine segment, which was apparently introduced by Hamilton...
in 1819, has been widely used to induce labor. Although it is rarely considered as method of induction of labor, it is frequently employed at term, especially where indications for induction are not strong enough. Uterine contractions are frequently established following the procedure resulting from the release of endogenous prostaglandins. Swann (1958) reported that when the cervix was favorable 69% of women would go into labor, if procedure was repeated daily for 3 days. It is a simple and useful method for women with a very good cervical score. If the procedure fails to induce labor within a few hours or a day, amniotomy can be performed.

**Amniotomy**

Hind water amniotomy with a Drew-Smythe catheter is hardly used in modern obstetrics. Amniotomy or artificial rupture of forewater, represents one of the most irrevocable interventions in pregnancy and calls for a firm commitment to delivery. Amniotomy alone would result in vaginal delivery in most women with a good cervical score. The main disadvantage being the occasional unpredictably long interval between the procedure and the onset of regular uterine activity. In current practice, amniotomy is usually combined immediately or after a variable interval, with intravenous oxytocin in order to reduce induction delivery interval.

**Use of Oxytocic Agents**

**Oxytocin**

Since the introduction of oxytocin as an intravenous infusion in the 1940s, it has come to be the most widely used method of induction of labor. The principles of current clinical usage of intravenous oxytocin are based on classic studies of Turnbull and Anderson (1968). These studies led to the concept of “titration” of oxytocin dosage in response to uterine contractions (Tables 2 and 3).

Customarily oxytocin dosage titration is based on the clinical feedback of labor ward staff on the characteristics of uterine contractions, their intensity, duration and frequency. There is still wide variation in the use of oxytocin, especially with regard to the initial starting dose, dose increment, rate of escalation and use of delivery system. Infusion solution varies from oxytocin 2.5–5 units per 500 mL of 5% glucose or Ringer’s lactate. The starting dose is usually 1–4 mU/minute and the dosage is subsequently increased every 30 minutes till effective contractions are established.

Throughout FHS are carefully monitored. Amniotomy is usually combined with oxytocin infusion during induction. Most obstetricians start with amniotomy followed immediately or within a few hours by oxytocin infusion. In cases with a high presenting part, it may be prudent to start the oxytocin infusion first and delay the amniotomy till effective contractions are established.

**Prostaglandins**

The most commonly used prostaglandins for cervical ripening and induction of labor are PGE2 preparations, which contain Dinoprostone. Two forms of PGE2 are available:

1. Dinoprostone tablets for oral use
2. Dinoprostone gel for intracervical instillations. Several randomized prospective studies have shown that PGE2 is more effective than oxytocin infusion for promoting vaginal birth. Oral PGE2 is started at a dose of 0.5 mg 1 hourly. The treatment is continued till labor is established or maximum of 8 tablets. Intracervical PGE2 may be repeated after 12–24 hours.

**Misoprostol**

Misoprostol (PGE1) is used for induction of abortion. In smaller doses, i.e. 25 µg it is also tried for induction of labor. However, the Cochrane Collaboration cites numerous reports if uterine rupture and fetal distress involving the drug use. The group concluded “It cannot be recommended for routine use at this stage.” The American College of Obstetricians and Gynecologists (ACOG) too issued guidelines in 2002 discouraging the use of misoprostol.

**Risks and Complications of Induction of Labor**

Induction of labor is a potentially hazardous obstetric intervention. There are three broad groups of risks associated with induction of labor:

---

### Table 2: Calculation of the dose delivered in milliunits (mU) and correlation with drop rate per minute

| Units of oxytocin mixed in 500 mL Ringer’s solution (1 unit = 1000 milliunits) (mU) | Drops per minute (15 drops = 1 mL) |
|---|---|---|
| | 15 | 30 | 60 |
| 1 | 2 | 4 | 8 |
| 2 | 4 | 8 | 16 |
| 8 | 16 | 32 | 64 |

1. The risk associated with terminating pregnancy artificially before the spontaneous onset of labor. These are:
   a. Failed induction leading to cesarean section
   b. Inadvertent preterm delivery.
2. Risks associated with artificial stimulation of uterine contractions, hyperstimulation which could lead to fetal distress, fetal death, rupture of uterus, precipitate labor with injuries.
3. Risks associated with specific method of induction:
   a. Amniotomy leading to cord prolapse, infection, rarely abruption in case of hydramnios.
   b. Use of oxytocin has been associated with an increased incidence of neonatal jaundice; prolonged infusion of relatively high doses of oxytocin in dilute solution can lead to maternal water intoxication.
   c. Use of prostaglandins can lead to gastrointestinal (GI) upsets, bronchospasm, pyrexia.

The most important decision to be made when considering induction of labor is whether or not the induction is justified.

“The spontaneous onset of labor is a robust and effective mechanism......and should be given to operate on its own. We should only induce labor when we are sure that we can do better.”

—Turnbull (1976)

BIBLIOGRAPHY

INTRODUCTION

Management of labor continues to be an area of keen debate even in present day obstetric practice. Widely divergent views are held amongst specialists with regard to the philosophy of labor. This is reflected in the attitude of obstetricians toward the mother in labor under his/her care. The views held by obstetricians regarding the place for delivery-home/nursing home/institution resulted in the “risk approach” and the separation of cases into low risk and high risk cases. All high risk cases being encouraged to book for institutional confinement. However, there is always an ever lurking danger of a low risk patient showing an unexpected turn of events and assuming alarming features necessitating special care.

There has always been a strident call from the women’s lobby as to why such a natural and physiological phenomenon like childbirth has been so medicalized that human childbirth has assumed worrisome proportions. Women are also questioning the rising incidence of cesarean section in present day practice, and wondering whether all the monitoring systems in place in modern obstetric practice are truly justified.

Partographic Documentation

Partographic documentation has been accepted as a standard method of clinical monitoring of labor. It has promoted the concept of “active management of labor” and shown the benefits of this approach in improving obstetric outcome. However, this can be practiced only in an institutional set-up.

Opinions regarding pain relief during labor also excite divergent and widely polarized views. There are the protagonists of the “laissez-faire” policy of leaving things entirely to nature. Many mothers do not wish that there should be any attenuation of the peak emotional experience and reality at the time of childbirth; they look forward to the event of the baby emerging through the birth canal, listening to the first cry and early bonding. Others, less tolerant seek relief in analgesics and epidural analgesia. In modern practice, obstetricians are witnessing an ever increasing demand for pain relief amongst parturients.

“The delivery of an infant into the arms of a conscious and pain free mother, is the most exciting and rewarding moments of the medicine.”

Obstetricians have also changed their attitudes toward labor. There is less of rigidity and regimentation, this is evident by the fact that women are now allowed to have a companion present during her delivery. She is allowed ambulation until she has progressed well into labor, birthing postures and procedures also reveal a more tolerant approach by the profession; similarly the attitude toward a routine episiotomy in all primigravida has also undergone a change, so that obstetricians are resorting to it less frequently than before.

ADMISSION PROCEDURE

The admission procedure should be discussed with the patient during the antenatal visits. She should be asked to report for admission when she starts getting pains which seem to be increasing in frequency/intensity, if there is presence of show or any leaking of the amniotic fluid.

In the admission room: The attending doctor checks her antenatal chart and makes note of any high risk factors. Special orders for any high risk factors should be clearly outlined and communicated to all staff members on duty.

On interrogation and examination, the following points are documented:
**History**

The gestation maturity as calculated on the basis of her menstrual dates.
- Time of onset of labor pains, their frequency, and intensity
- Presence of show/leaking
- Time of consuming the last meal.

**General Examination**

- Document her total peripheral resistance and blood pressure on admission
- Auscultate the heart sounds and lungs
- Check for clinical pallor—tongue/conjunctivae.

**Obstetric Examination**

- Check the fundal height in centimeter
- Palpate the abdomen for fetal presentation and position
- Note the position of the anterior shoulder and auscultate the fetal heart rate (FHR)
- Observe the uterine contractions (palpation) for intensity, duration and frequency. Note alteration of FHR at height of pains and recovery time
- Perform a vaginal examination with full aseptic precautions and document the following:
  - The position of the cervix, its dilation in cm and extent of effacement (Table 1)
  - Presence or absence of the membranes, if leaking is present
  - Nature of amniotic fluid—clear/meconium present
  - The station of the presenting part, degree of flexion and how well it is applied to the fetal head
  - Assess fetopelvic relationship. Try to rule out any disproportion.

**Admission Orders**

The conventional enema and vulval shaving are often waived; however, it is advisable to clip the hair short, a dulcolax suppository ensures satisfactory bowel evacuation, this prevents soiling of the perineum during birth of the baby.
- A warm water bath, followed by a clean linen gown
- A sterile pad should be given and the patient admitted to the waiting ward. She should be encouraged to walk around, partake of easily digestible foods and clear fluid nourishment
- The FHR should be checked every hour. An admission documentation of the electronic FHR recording (Admission-test), if normal, is very reassuring of how the baby will fare during the course of labor. An abnormal tracing is often a harbinger of adverse events that are likely to arise, and alert the clinician to be very careful during the course of labor
- When the frequency of pains increases to 3/10 minutes lasting for 30–40 seconds, an internal examination to check the progress of labor is desirable. Should the patient have entered the “active phase” of labor, it is essential that the patient be transferred to the labor room for closer observation, and administration of any medication that may be necessary to procure pain relief.

**First Stage of Labor**

Clinical observations should be meticulous when the patient enters the active phase of labor. At this stage the patient complains of regular pains of good intensity every 3–4 minutes lasting for about 30–40 seconds. Often there is presence of show or passage of fluid discharge, the intensity of pain increases sufficiently, so that most patients generally ask for pain relief at this stage. The cervix is about 3–4 cm dilated and well-effaced.
- Commence a partogram and document all labor events, clinical observations and medications on this chart (Fig. 1)
- Clinical FHR monitoring is an ongoing observation of human fetal physiology, for years, obstetricians have depended on it for assessing fetal health during parturition, even in the present times, this method of monitoring the fetal status in low risk cases continues to provide satisfactory results; however, in high risk...

*In modified Bishop’s scoring, cervical length replaces effacement (cm)
mothers—electronic FHR surveillance (cardiotocography) provides a superior means of assessing fetal oxygenation status

- Cardiotocography recordings should be commenced if desired (continuous or interrupted)
- Fetal heart rate recorded periodically (auscultation/cardiotocography) every 15–30 minutes until she reaches the second stage of labor
- An amniotomy is desirable. This accelerates labor, and clear amniotic fluid is reassuring to the obstetrician. However, if there is presence of meconium, it puts the attending staff on guard
- The choice of analgesia is left to the mutual decision of the patient and the attending obstetrician
- When the patient experiences strong repetitive contractions, and experiences bearing down pains, she is often in the second stage of labor.

**Second Stage of Labor**

The onset of the second stage of labor is recognized by the bearing down efforts of the patient, often the membranes rupture spontaneously at this time. Vaginal examination confirms full dilatation of the cervix. The membranes should be ruptured if as yet intact. Observe for passage of meconium, exclude cord prolapse/compound presentation. Note the position of the occiput in cephalic presentations and the degree of head flexion. Check for disproportion and document the station of the presenting part. The FHS is checked, the patient should be transferred to the labor ward for close monitoring.

The patient is encouraged to assume the lateral position, when she feels the urge to bear down and the perineum begins to stretch, the patient is encouraged to lie down on her back, she is encouraged to bear down with the pains, the FHS are checked after each pain and the perineum observed, the introitus progressively opens up, and the perineum is put on an increasing stretch. Obstetricians prefer to avoid the use of episiotomy; however, in case of impending tear, an episiotomy performed after local infiltration with 1% xylocaine for local anesthesia prevents bad perineal tears. After the head is born, the mouth is cleaned, a finger passed around the fetal neck to detect presence of nuchal cord loops, if present—the cord loop should be loosened or divided between clamps. With further pains the shoulders and the trunk follow. In modern times, women are encouraged to assume the positions of their choice at the time of child birth; these may require the obstetrician to adapt to the patient's needs.

**Third Stage of Labor**

Modern management of the third stage of labor involves "active management" of the third stage of labor. This method employs the use of oxytocic drugs to hasten placental separation and expulsion and to minimize the blood loss attending the third stage of labor. The drugs used include the following:

- Injection methergin (methyl ergometrine) 0.25 mg slowly intravenously (preferably diluted) at the time of crowning of the fetal head/delivery of the anterior shoulder.
- Injection oxytocin (pitocin) 10 units diluted in 10 mL of physiological saline/5% glucose into the umbilical vein, soon after the baby is born and the cord clamped and cut
- Injection PGE₂ 125 µg intramuscularly soon after birth.

The placenta usually separates within a few minutes, and is delivered by controlled cord traction. The blood loss is often minimized to about 50 mL. Details of commonly used uterotonic agents for the “Active Management of the Third Stage of Labor” are shown in Table 2.

**Active management of third stage of labor:**

**Principle:** To excite powerful uterine contractions within 1 minute of delivery of the baby (WHO) by giving parenteral oxytocics.

**Advantages:**

- Minimize blood loss in third stage approximately to one-fifth
- To shorten the duration of third stage of labor to half

**Medications**

- 5% glucose infusion
- Inj. Tramadol 50 mg + Inj. Drotin 80 mg IM
- Inj. Pentazocine HCl 6 mg + Inj. Diazepam 2 mg slow IV—oral Primiprost Tab. 1 hourly
Disadvantage: Slight increased incidence of retained placenta and consequent increased (1–2%) incidence of manual removal.

Components:
- Use of oxytocics within 1 minute following the delivery of baby.
- Controlled CORD traction.
- Uterine massage.

**PARTOGRAPHY**

The concept of recording the progress of labor graphically introduced by Friedman (1955) resulted in the construction of the now famous “Sigmoid” curve known as the “cervical dilatation—time curve” (Fig. 2). Philpott and Castle (1972) demonstrated the importance of its clinical application in developing countries to identify “dystocic labors.” The partogram has now become an accepted mode of documenting the events in labor. In India, a partogram for primigravidae based on Indian data was created by Daftary and Mhatre (1977); this nomogram can be utilized for comparison with the patient’s partogram to detect early deviation from the normal expected progress in labor and to alert the attending clinician in good time about possible developing problems, to enable him to institute timely corrective measures.

Similar “nomograms” created by Studd JW (1973) has helped to identify problems early, to seek timely help/transfer the patient to a better facility in time. The incidence of maternal morbidity/mortality has thus been reduced considerably, and at the same time the perinatal outcome has been improved. This policy has not increased the rates of cesarean sections unduly (Fig. 3).

**ACTIVE MANAGEMENT OF LABOR**

The concept of “active management of labor” first advanced by O’Driscoll & the Irish master has received wide acceptance. This policy depends upon the vigilant observation of the progress of labor and timely intervention when delay is detected. It requires the cooperation of a well-trained nursing staff and experienced clinicians. It is well-established that prolonged labors predispose to infection, dehydration, ketosis, exhaustion and disillusionment in the mother, as well as fetal distress and increased morbidity in the unborn baby. The Irish workers have demonstrated that with the implementation of this policy, most primigravidae can be delivered within 12 hours of admission and multiparae within 6 hours. Obstetric
Fig. 3: Partogram (modified WHO) representing graphically the important observations in labor. The cervix dilatation and descent of head are shown in relation to alert and action lines. Intensity and duration of uterine contraction are shown with shades.
outcome is significantly improved, maternal morbidity reduced, perinatal outcome improved and the rates of cesarean sections reduced. The widespread use of amniotomy and oxytocics to optimize pains coupled with judicious use of analgesics help to ensure steady progress of labor, reduce the risks of dysfunctional labor and enable early identification of emerging obstetric problems.

**Obstetric Analgesia**

Women have suffered from the pangs of childbirth through centuries, enlightened physicians have been concerned with alleviating labor pain; however, the attitude toward providing pain relief has been conflicting. Many of the drugs used earlier have been known to cause respiratory depression in the newborn and require to be used with caution. Epidural anesthesia provides excellent relief without unduly jeopardizing the labor outcome. Pain relief is known to allay fear and anxiety and provide a more favorable environment for improved obstetric outcome. For the mother it provides relief from pain, controls alterations in circulation, ventilation and undue muscular efforts. It ensures better patient cooperation. For the fetus, labor analgesia means shorter and less traumatic labors, protection against hypoxia and fetal depression at birth, and protection against needless instrumental-assisted delivery necessitated by maternal distress. To the obstetrician, it provides a better control over events emerging during the course of labor, reduces the pressures from the patient and relatives to intervene, and ensures optimum conditions to prevail at the time of childbirth. Epidural anesthesia requires the services of a trained anesthesiologist; it can be employed in institutional deliveries, requires qualified staff for constant supervision and is expensive. Such facilities are available in a few institutions in metropolitan towns. For the vast majority of women in our country—this is still a distant dream. However, indigenous protocols to provide pain relief in labor have been developed in our country, which can be adopted by obstetricians in their own practices to provide pain relief in labor, ensure freedom from fear of childbirth and improve obstetric outcome. One such protocol developed at the Nowrosjee Wadia Maternity Hospital in Mumbai, and extensively evaluated in our country by the author and his colleagues aims at the use of drugs for pain relief programmed to be used in accordance with the progress already achieved, so that the excruciating pain of labor is mitigated, cervical dilatation is facilitated, and the incidence of dysfunctional labors is reduced. An improved obstetric outcome is obtained by adopting the principles of programmed labor, whilst at the same time reducing the need for obstetric interventions.

**PROGRAMMED LABOR**

This protocol developed by Daftary SN et al. (2001), rests on three pillars as outlined under.

- Ensure adequate pains—amniotomy, and/or use of prostaglandins/oxytocin infusion to ensure that the patient gets three sustained contractions/10 minutes intervals/lasting 35–45 seconds. The FHR pattern is satisfactory and the uterus relaxes well between pains.
- Ensure pain relief—epidural anesthesia may be used, if available. In absence of this facility, suitable combination of analgesic drugs can be gainfully employed to provide reasonable pain relief, freedom from anxiety and patient cooperation. When the patient is in established labor and reaches about 4.0 cm dilatation, the patient is closely observed in the labor ward, and partographic documentation implemented.
- Set-up an intravenous infusion line using ringer lactate solution. Administer a small dose of 2.0 mg diazepam + 6.0 mg pentazocine diluted in 10 mL of saline, slow intravenously as a bolus to initiate pain relief. This dose is so small that it does not affect the mother or the fetus adversely. Now administer injection tramadol 50.0 mg intramuscularly in thin patients. If the patient’s weight is over 60 kg, increase the dose to 1.0 mg/kg maternal body weight. Along with the tramadol, combine it with a smooth muscle relaxant (drozin, anafortan, buscopan epidosin as per clinician’s choice). The combined drug effect provides excellent pain relief and facilitates cervical dilatation. The labor progresses satisfactorily until the head comes down onto the pelvic floor. At this time the cervix is close to full dilatation and the station of the presenting part in the lower pelvic strait. Should the pains be strong and distressing, it is safe to administer ketamine in analgesic dose not exceeding 0.5 mg/kg maternal body weight after proper counseling. Generally in practice, an initial dose of 10 mg administered diluted and slowly often suffices. This medication provides marked analgesia and amnesia. The drug is short acting (effect wears off in about 20 minutes), in case further pain relief is required, a top-up-dose of half the initial loading dose may be repeated as required. Although, ketamine crosses over into the fetal circulation, it is rapidly metabolized and does not depress the respiratory center. After birth, if the baby does not cry lustily, ventilatory support with bag and mask is generally all that is required. Until the team of clinicians gets familiar with the use of ketamine, it is recommended to have an anesthesiologist stand by. During the third stage of labor, the practice of active management is recommended.
- After expulsion of the placenta, inspect the birth canal and perineum for any injuries and repair the same. A single dose of injection ketamine after delivery permits easy
examination of the birth canal and permits easy surgical repair of episiotomy/tears and lacerations.

Clinical Experiences with Programmed Labor

- **Programmed labor**: Daftary SN,11 Desai SV, Nanavati MS, Bhide AG, Patki AS, and Levi JM (Mumbai). They analyzed the experiences of their pooled data based on labor outcome of low risk patients, which included 800 primigravidae and 600 multigravidae.

  They reported normal vaginal deliveries in 90.4% of primiparas and 94.5% of multiparas, low forceps and ventouse assistance in 9.59% of primis and 3.5% of multiparas. The cesarean section rate in primigravidae was 9.6% and in multiparae it was 4.5%. The average duration of labors in primigravidae was 9.1 hours and in multiparae it was 5.8 hours. The mean rate of cervical dilatation during active labor was 2.2 cm/hour in primis and 2.8 cm/hour in multiparas.

  Partograms revealed the duration of the active phase of labor to be 3.5 hours in the primigravidae and 2.4 hours in multipaer. The third stage of labor lasted between 4 minutes and 6 minutes. The APGAR scores at the end of 5 minutes was less than 7 in 1.2% of primis and in less than 0.3 of multis. There was no perinatal loss.

- Hema Divakar12 and Anupama Patil of Bangalore analyzed their data on cases treated as per the programmed labor protocol and concluded that 85% of patients experienced substantial pain relief. The duration of labors was much curtailed, the obstetric interventions did not increase, they reported a cesarean section rate of 4.5% and a vaginal assistance rate of 6%, the neonatal outcome was satisfactory, and there was no perinatal loss. Maintenance of the partogram helped in early identification of emerging obstetric problems, alerting the clinician to adopt timely corrective measures.

- **A clinical study of programmed labor and its outcome**: Chauhan R, Gupta A13 from Jubbalpore, reported on their experience of 75 cases which included 25 primiparae and 50 multiparae. They reported the mean time for onset of analgesia to be around 16 minutes. Satisfactory pain relief was experienced by 88% of primiparae and 92% of multiparae. The mean duration of the first stage of labor was 3.4 +/- 1.55 hours in primis and in multiparae it was 2.50 +/- 1.25 hours which was significantly lower than in controls observed as 4.50 +/- 1.20 hours in primis and 3.58 +/- 1.47 hours in multis. In their study, 92% of primiparae and 98% of the multiparae had normal vaginal delivery. The duration of the third stage was 3–5 minutes. The total blood loss was much reduced. The APGAR scores were satisfactory in all patients in the treatment group.

- Priyanki Kadakia14 and Ragini Verma undertook a study of 90 parturients adopting the programmed labor protocol for labor analgesia at Government Medical College Surat. A summary of their experience is presented:
  - The study included 90 cases.
  - Sixty-two percent of the patients were aged between 17 years and 25 years.
  - Mean weight of the patients was 52.3 kg
  - Primiparas accounted for 49 cases and multiparae were 41.
  - 95.5% of cases delivered within 4 hours of commencing analgesia.
  - Mean time of onset of analgesia was 3.56 minutes.
  - 74.4% patients experienced substantial pain relief whilst in 10% pain relief was excellent.
  - 97.8% patients had normal deliveries.
  - The rate of cervical dilatation achieved was 1.9 cm/hour in primigravidae and 2.8 cm/hour in multiparae.
  - The FHRs and APGAR scores after birth remained unaffected.
  - Maternal vital parameters were unaffected.
  - Minor side effects like nausea, vomiting, drowsiness, and malaise were observed in 23 (25.5%) cases. None suffered any serious side-effects.

  The ease of administration, the need for minimal patient monitoring with systemic analgesia made programmed labor protocol highly acceptable. In the year 2005, FOGSI President Dr SV Desai propagated the theme of “Optimizing Labor outcome for safe motherhood” based on the above protocol using the Indian partogram. The illustrative cases shown below amply demonstrate the value of using the above management protocol.

**ILLUSTRATIVE CASES**

**Case 1**

Mrs D Khanna, aged 21 years, Primigravida—38 weeks pregnant, vertex (head down) position. No antenatal risk factors. On 12/5/03 at 10.00 am—labor induced with cerviprime gel. Admitted in labor at 2.00 pm. Patient given oral tablet of primiprost at 1 hourly interval to augment labor. At 4.00 pm, patient entered the “active phase” of labor. Further progress of labor recorded on the “partogram”. Figures 1, 2 and 4 show partograms at different stages in labor.

**Conclusion**

Short labor, pain relief—substantial; amnesia: fair; short third stage, reduced blood loss. Mother and baby well.

**Case 2**

Mrs M Pujari aged 25 years, Primigravida, 39 weeks pregnant, vertex (head down) position. No antenatal risk factors. On 22/11/02 at 5.00 am labor induced with cerviprime gel. Labor pains commenced at 8.00 am. Patient entered the “active phase” of labor at 9.30 am.

**Charting of Partogram Commenced**

All further events are shown on partograms (Figs 5 to 7).

Conclusion

Patients partogram to the left of the nomogram indicates rapid progress and also helps in the following:
- Marked reduction in duration of labor
- Patient experienced considerable pain relief
- Patient able to bear down and deliver normally
- Marked reduction in third stage of labor
- Minimal blood loss in the third stage
- Condition of mother and baby satisfactory after delivery
- Minimal memory of labor events.

DYSFUNCTIONAL LABOR

This is diagnosed when the patient in active labor fails to accomplish cervical effacement and dilatation at an acceptable rate in the first stage of labor, or fails to accomplish descent of the presenting part at an acceptable rate in the second stage of labor. Before making any treatment plans, a series of diagnostic questions need to be answered as summarized in Table 3.

REFERENCES

INTRODUCTION

With the invention of the stethoscope (1810) physician could hear the fetal heart beat. However, the instrument could not detect subtle changes or provide continuous surveillance. These deficiencies were overcome in 1968 with the development of electronic fetal monitoring (EFM). The hope was that it would help physicians to diagnose fetal hypoxia, or lack of oxygen in time to prevent perinatal neurologic damage. By the early 1990s, more than 75% of the nation’s birth attendants had switched from intermittent auscultation (IA) to EFM.¹

Intrapartum fetal monitoring can be performed by:
1. Intermittent auscultation
2. Electronic fetal monitoring:
   • External (indirect) (Fig. 1)
   • Internal (direct) (Fig. 2)
3. Other intrapartum fetal monitoring techniques:
   • Fetal scalp blood sampling (FBS)
   • Scalp stimulation
   • Vibroacoustic stimulation
   • Fetal pulse oximetry
   • Fetal electrocardiography

Fig. 1: External monitoring uses two belts placed around the woman’s abdomen

Fig. 2: Internal monitoring uses two devices placed inside the uterus. One is attached to the fetus
consensus regarding the definition of “fetal distress” has not been established. Hypoxia with acidosis (often referred to as asphyxia although originally the term simply meant born without an evident pulse, from the Greek asphyxos) is widely perceived to be the most important cause but does not have a simple relationship with condition of baby at birth. According to ACOG (1991), birth asphyxia is defined as “intrapartum hypoxia sufficient to cause neurologic damage” as evidenced by:

- Umbilical artery pH less than 7.00
- Five-minute Apgar score less than or equal to 3
- Moderate or severe neonatal encephalopathy
- Multiorgan dysfunction [e.g. cardiovascular system (CVS), renal, pulmonary].

Birth asphyxia has also been implicated as a cause of cerebral palsy, although most cases of cerebral palsy occur in persons without evidence of birth asphyxia or other intrapartum events. The ACOG Task Force (2003) on neonatal encephalopathy and cerebral palsy stated the criteria to define an acute intrapartum event sufficient to cause cerebral palsy.

### Essential Criteria (Must Meet all Four)

- Evidence of metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH < 7 and base deficit ≥ 12 mmol/L)
- Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks of gestation.
- Cerebral palsy of the spastic, quadriplegic or dyskinetic type.
- Exclusion of other identifiable etiologic disorders such as trauma, coagulation, infectious conditions or genetic causes.

Criteria that collectively suggest an intrapartum timing (within close proximity to labor and delivery, e.g. 0–48 hours) but are nonspecific to asphyxial insults:

- A sentinel (signal) hypoxic event occurring immediately before or during labor.
- A sudden and sustained fetal bradycardia or the absence of FHR variability in the presence of persistent, late or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal.
- Apgar scores of 0–3 beyond 5 minutes.
- Onset of multisystem involvement within 72 hours of birth.
- Early imaging study showing evidence of acute nonfocal cerebral abnormality.

The fetus does not become acidotic as soon as the FHR becomes abnormal. Fleischer and associates showed that a well-grown fetus can cope with hypoxic stress for as long as 90 minutes before the pH of fetal blood starts to fall. Thus, a normal fetal scalp blood pH 60 minutes after the cardiotocography (CTG) has become abnormal does not indicate that the abnormality is a “false positive.”

---

### Table 1: Guidelines for methods of intrapartum fetal rate monitoring

<table>
<thead>
<tr>
<th>Surveillance</th>
<th>Low-risk pregnancies</th>
<th>High-risk pregnancies</th>
</tr>
</thead>
</table>

**Acceptable methods**

- Intermittent auscultation: Yes
- Continuous electronic monitoring (internal or external): Yes

**Evaluation intervals**

- First-stage labor (active): 30 minutes
- Second-stage labor: 15 minutes

---

#### LIMITATIONS

- Intrapartum Doppler velocimetry
- Cord blood gases (CBGs) for acid-base assessment (Table 1).

#### ELECTRONIC FETAL MONITORING

**External or Direct Monitoring**

Since its inception, the primary objective of EFM has been to identify the fetal distress so that measures might be taken to avert permanent fetal damage or death. However, the clear
Indications for Electronic Fetal Monitoring

- **Antenatal maternal conditions:**
  - Hypertension/hypertension with adverse condition
  - Diabetes
  - Antepartum hemorrhage
  - Other maternal medical disease
- **Antenatal fetal conditions:**
  - Growth-restricted fetus
  - Prematurity
  - Oligohydramnios
  - Abnormal umbilical artery Doppler velocimetry
  - Isoimmunization
  - Multiple pregnancy
  - Breech presentation
- **Intrapartum maternal conditions:**
  - Vaginal bleeding in labor
  - Intrauterine infection
- **Labor:**
  - Previous cesarean section
  - Prolonged membrane rupture
  - Induced labor
  - Augmented labor
  - Hypertonic uterus
- **Fetal conditions:**
  - Meconium-stained amniotic fluid
  - Post-term pregnancy
  - Suspicous (nonreassuring) FHR on auscultation.
- **Fetal health surveillance may not be warranted, if:**
  - Extreme prematurity (< 23 weeks)
  - Lethal fetal anomalies (e.g. anencephaly)

**Interpretation of Fetal Heart Rate Recording**

The key to reliable and consistent interpretation of FHR tracings from CTG machines is a systematic approach.

Four main aspects of the FHR should be assessed:

1. The base line rate
2. Baseline variability
3. The presence or absence of accelerations
4. The presence and classification of decelerations.

Many errors of interpretation occur because of an excessive concern with decelerations and a failure to appreciate the significance of the other three aspects of the FHR.

A detailed account of how the FHR can be assessed using CTG is given below in Tables 2 and 3.

**Current Recommendations of Electronic Fetal Monitoring**

The methods most commonly used for intrapartum FHR monitoring include IA or continuous electronic monitoring of the heart rate and uterine contraction.

- However, more recently, a number of systematic reviews, of randomized controlled trials (RCTs) have been published that do not support the routine use of EFM, especially in low-risk women. The data show that neurologic abnormalities are not caused by intermittent episodes of asphyxia that commonly occur during labor.

- The most recent meta-analysis by Cochrane Collaboration concluded that a statistically significant decrease in neonatal seizures was associated with routine continuous EFM. The authors, however, observed no significant difference in 1-minute Apgar scores below four, 1 minute Apgar score below seven, rate of admissions to neonatal intensive care units, or perinatal death. Women whose labors were monitored with EFM had an approximately 40% increased risks of cesarean delivery and 20% increased risk of operative vaginal delivery compared with women who received IAs.

- Despite the increase in neonatal seizures in children born after IA in the Dublin Randomized trial of intrapartum monitoring at follow-up at 4 years of age, there were no differences between the two groups with regard to the proportion of children who developed cerebral palsy.

- Meta-analysis of randomized clinical trials indicate that EFM changes indicating nonreassuring fetal status have poor predictive value i.e. there is high false positive rate which leads to increased operative deliveries (with or without FBS). Normal EFM tracing have a high predictive
Intrapartum Management

Table 3: Pathologic/ominous cardiotocography (CTG)

- Baseline fetal heart rate (FHR) more than 150 beats/minute and silent pattern and/or repetitive late or variable decelerations
- Silent pattern for more than 90 minutes
- Complicated variable decelerations (depth ≥ 60 beats/minute, duration ≥ 60 seconds) and changes in shape (over shoot decreased or increased baseline heart rate following the decelerations; absence of baseline variability, slow recovery)
- Combined or biphasic decelerations (variable followed by late)
- Prolonged bradycardia (FHR drops to < 80 beats/minute for > 2 minutes or < 100 beats/minute for > 3 minutes) more than 10 minutes
- Repetitive late decelerations
- Pronounced loss of baseline variability
- Sinusoidal pattern with no accelerations

Interpretation or action: Consider fetal scalp pH estimation (first stage expedite delivery if not imminent (second stage).

Internal or direct monitoring

- Indications:
  - External tracing inadequate for accurate interpretation
- Contraindications:
  - Placenta praevia
  - Face presentation
  - Unknown presentation
  - Human immunodeficiency virus (HIV) seropositive
  - Active genital herpes
  - Hepatitis B and C virus infection.

- The FHR is measured by attaching a bipolar spiral electrode directly to the fetus (Fig. 2). The wire electrode penetrates the fetal scalp and the second pole is a metal wing on the electrode. Vaginal body fluids create a saline electrical bridge that completes the circuit and permits measurements of the voltage differences between the two poles. The electrical fetal cardiac signals—P wave, QRS complex, and T wave—are amplified and fed into a cardiotachometer for heart rate circulation.

Disadvantages

If the fetus is dead, the weaker maternal signal will be amplified and displayed as the "FHR".

Other intrapartum fetal monitoring techniques

Fetal scalp blood sampling allows for determination of the fetal acid-base status during labor. According to the ACOG (1995b) measurements of the pH in capillary scalp blood may help to identify the fetus in serious distress.

Indications

- A confusing/nonreassuring FHR pattern is present with elements suggestive of fetal hypoxic acidemia, e.g. uncorrected late deceleration with average variability, or combined patterns of late or variable declarations with decreased variability.
- Variability less than or equal to 5 bpm with/without periodic changes.
Intrapartum Fetal Monitoring Controversies

Chapter 33

Intrapartum Fetal Monitoring Controversies

Fig. 3: Reassuring pattern. Baseline fetal heart rate is 130–140 beats per minute (bpm), preserved beat-to-beat and long-term variability. Accelerations last for 15 or more seconds above baseline and peak at 15 or more bpm. (Small square=10 seconds; large square=one minute)

Fig. 4: Saltatory pattern with wide variability. The oscillations of the fetal heart rate above and below the baseline exceed 25 bpm

Fig. 5: Early deceleration in a patient with an unremarkable course of labor. Notice that the onset and the return of the deceleration coincide with the start and the end of the contraction, giving the characteristic mirror image

Fig. 6: Nonreassuring pattern of late decelerations with preserved beat-to-beat variability. Note the onset at the peak of the uterine contractions and the return to baseline after the contraction has ended. The second uterine contraction is associated with a shallow and subtle late deceleration

- Sinusoidal pattern.
- Fetal cardiac arrhythmias.
- Mixed deceleration pattern which complicates interpretation.

Fetal Scalp Blood Sampling not Indicated When
- Electronic fetal monitoring is reassuring (Fig. 3).
- Nonreassuring EFM patterns suggest significant fetal decompensation requiring immediate delivery (Figs 4 to 11).

Contraindications
- Mother is a known carrier of hemophilia and fetus is either affected or of unknown status.
- Mother is HIV seropositive.
- Active maternal genital infection. (e.g. Herpes).

Classification of Fetal Scalp Blood Sampling Results
The classification of FBS results is shown in Table 4. During labor, a normal scalp pH is 7.25 to 7.35. Value of less than 7.25 indicates acidosis.

Disadvantages
- The method is time consuming and inconvenient to the obstetrician and patients.
- The procedure is difficult to perform if cervix is undilated, multiple sampling is required, maintenance of blood gas analyzer is not easy.
Advantages
The rising incidence of cesarean section with introduction of FHR monitoring was definitely reduced with the addition of scalp pH monitoring. 

Scalp Stimulation
Scalp stimulation is an alternative to FBS. This proposal was based on the observation that acceleration of the heart rate in response to pinching of scalp with an Allis clamp just prior to obtaining blood was invariably associated with a normal pH. Conversely, failure to provoke acceleration was not uniformly predictive of fetal acidemia. Fetal acceleration of 15 beats per minute for 15 seconds is seen in response to fetal scalp pH greater than or equal to 7.19. Among fetuses without an acceleratory response to scalp stimulation, 39% were considered acidotic (pH < 7.19).

Vibroacoustic Stimulation
Fetal heart rate acceleration in response to vibroacoustic stimulation has been recommended as a substitute for scalp sampling. This technique involves the use of an electronic artificial larynx placed a centimeter or so from, or directly onto, the maternal abdomen. FHR acceleration of at least 15 beats/minute for at least 15 seconds occurring within...
15 seconds after the stimulation and with prolonged fetal movements is considered normal. This technique is an effective predictor of fetal acidosis in the setting of variable decelerations. However, the predictability for fetal acidosis in the setting of late decelerations is limited. Vibroacoustic stimulation in second stage of labor is associated with FHR reactivity, but the quality of the response did not predict neonatal outcome or enhance labor management.

A meta-analysis of reports on intrapartum fetal stimulation tests published between 1996 and 2000 showed that results of all four types of tests like scalp puncture for pH testing, an Allis clamp to pinch the fetal scalp, vibroacoustic stimulation, and digital stroking of the scalp were similar. They concluded that intrapartum stimulation tests were useful to rule out fetal acidemia. However, they cautioned that these tests are “less than perfect”.

**Fetal Pulse Oximetry (Fetal Oxygenation)**

In 1994, fetal oximetry was marketed in countries outside the United States (US) including Europe and Canada. In January 2000, the Obstetrics and Gynecology Devices Panel of the Medical Devices Advisory Committee of the Food and Drug Administration (FDA) recommended approval of a fetal oximeter for use in Obstetrics (Oxifirst: N-400 Fetal Oxygen monitoring system Nellcor). The aim of fetal pulse oximetry is to provide a continuous assessment of fetal oxygen saturation. In this method, a sensor is placed transvaginally between the uterine wall and fetal face which measures oxyhemoglobin saturation (Fig. 12). The lower limit for normal fetal oxygen saturation is generally considered to be 30% by most investigators. In a US multicenter randomized, controlled trial of fetal oximetry showed that the rate of cesarean delivery for fetal distress was significantly lower in fetal pulse oximetry group 4.5% compared to 10.2% in the conventional fetal-monitoring group. However, the cesarean rate for dystocia was significantly higher in the oximetry group (18.5%) versus 8.6% in the control group. Thus, the overall cesarean rate were not different (29% oximetry plus EFM vs 26% EFM).

According to ACOG (2005), an ancillary test of fetal status, fetal pulse oximetry, is associated with a significantly lower rate of cesarean delivery. However, because of concerns about false reassurance of fetal oxygenation, use of fetal pulse oximetry is not recommended at this time.

**Fetal Electrocardiographic Wave Form Analysis**

Since the fetal electrocardiogram (ECG) was first demonstrated by Cremer in 1904, attempts have been made to assess fetal well-being by assessing changes in ECG waveform. One approach has been to analyze changes in the PR/RR interval ratio but this has not been found to be of value in a prospective RCT. Another approach used the T/QRS ratio as a measure of acidosis (based on hypothesis that it is altered by the production of lactate in the fetal heart secondary to hypoxia) and can reduces the need for FBS. Two prospective RCTs suggested that it can reduce the need for operative delivery for fetal distress, metabolic acidosis and neonatal encephalopathy. In ST segment changes monitoring, infants outcomes were not improved compared with those with use of conventional fetal monitoring alone, although there was a reduction in the cesarean delivery rates for fetal distress. ST analysis to conventional fetal monitoring significantly reduced cesarean delivery rates for fetal distress as well as metabolic acidemia in umbilical artery blood (Flow chart 1).

However, a recent study of its introduction into routine clinical practice did not show the expected benefits.31

**Flow chart 1: Intrapartum fetal monitoring**

![Flow chart 1: Intrapartum fetal monitoring](image-url)
Intrapartum Doppler Velocimetry

Doppler analysis of the umbilical artery has been scheduled as another potential adjunct to conventional fetal monitoring. But according to reviewed literature, this technique was a poor predictor of adverse perinatal outcomes.62

Cord Blood Gases for Acid-base Assessment

The Society of Obstetricians and Gynecologists of Canada (SOGC) suggests the CBGs for the acid-base assessment sample to be obtained at all births.11 This can be done by various method as transcutaneous gas measurements, percutaneous umbilical blood sampling and clamped segment of cord. Acid-base tests (pH, base excess pCO₂, pO₂, O₂ saturation) can be done to clarify if acidosis is metabolic or respiratory. However, pO₂ is not reliable on cord blood.63

Apart from these, fetal scalp lactate measurement tried. This can be done by various methods.64

Further investigation will be needed to address the role of intrapartum fetal surveillance in uncomplicated, low-risk pregnancies.

CONCLUSION

- Routine EFM is not recommended for low-risk women in labor when adequate clinical monitoring including IA by trained staff is available. There are insufficient evidences to recommend for or against EFM over IA for high-risk pregnancies.
- Electronic FHR monitoring in high-risk labors produces significant effect in short-term neonatal morbidity and a significant reduction in perinatal deaths due to hypoxia but a significant increase in cesarean section rates; but all studies were insufficiently robust to be able to demonstrate any effect on perinatal mortality or cerebral palsy rate.
- Human errors (especially delays in response time and interpretation) contribute to poor outcome in monitored labors.
- Further investigation will be needed to address the role of intrapartum fetal surveillance in uncomplicated, low-risk pregnancies.

REFERENCES

INTRODUCTION

Every year it is estimated that worldwide, more than 500,000 women die of complications of pregnancy and childbirth. At least 7 million women who survive childbirth suffer serious health problems and a further 50 million women suffer adverse health consequences after childbirth. The overwhelming majority of these deaths and complications occur in developing countries. Temptations to expedite delivery by the vaginal route may pose problems when the conditions are suboptimal and the case may be one of obstructed labor, a serious pregnancy-related complication. For each woman who dies, at least 30 and an estimated of 100 women survive childbearing but suffer serious disease, disability or physical damage if the case is of obstructed labor. Obstructed labor contributes 3–5% of hospital admissions. Eight percent of all maternal deaths in developing countries are due to obstructed labor. 

Obstructed labor means that, in spite of strong contractions of the uterus, the fetus cannot descend through the pelvis because there is an insurmountable barrier preventing its descent. Obstruction usually occurs at the pelvic brim, but occasionally it may occur in the cavity or at the outlet of the pelvis. Complications resulting from obstructed labor can be avoided by a woman if obstructed labor is identified early and appropriate action is taken.

ETIOLOGY

Obstructed labor is defined as an arrest of vaginal delivery of fetus due to mechanical obstruction and professional assistance is required for the further management. The causes can be classified as:

**Maternal Causes**

**Bony Contraction**
- Contracted pelvis
- Tumors of pelvis
- Bony deformities

**Soft Tissue Obstruction**
- Uterine-impacted fibroid
  - Constriction ring
  - Sacculation of uterus
• Cervical-stenosis, tumors
  – Vaginal-stenosis, septa, tumors
  – Ovarian-neoplasm

Others
• Pelvic kidney
• Tumors of urinary bladder and rectum
• Vesical calculus

Fetal Conditions
• Large size baby (macrosomia)
• Malpresentations and malpositions
• Locked twins
• Fetal anomalies in babies

What Happens in Obstructed Labor?
It is important for students and learning obstetricians to understand what happens when labor is obstructed. The various consequences of obstructed labor are as follows (Fig. 1).

• Premature rupture of membranes: When the head is arrested in the pelvic inlet, the entire force exerted by the uterus acts directly upon the portion of membranes in contact with the internal os. Consequently early rupture of membranes is likely.

• Abnormalities in dilatation: The cervix dilates slowly or not at all, because the fetal head cannot descend and put pressure on it. At the same time the cervix may become edematous. The first stage of labor is therefore prolonged. (However, the first stage may be normal or short if, for example, obstruction occurs only at the outlet. In this case only the second stage will be prolonged). Prolonged labor causes the mother to become ketoacidotic and dehydrated.

  An undilating cervix means that a cesarean will be necessary. On the other hand, if the cervix is dilating normally, this usually indicates that the obstruction has been overcome by labor and that vaginal delivery will be possible (provided there is no outlet obstruction).

• Danger of uterine rupture: When the membranes rupture and the amniotic fluid drains away, the fetus is forced into the lower segment of the uterus by contractions. If the contractions continue, the lower segment stretches, becomes dangerously thin and is likely to rupture (However, uterine exhaustion may occur before that point is reached, causing contractions to become weaker or cease altogether and making the occurrence of uterine rupture less likely) (Fig. 2).

  Rupture of the uterus is more likely to occur in multipara (it is very rare in nullipara), especially if the uterus is already weakened by the scar of a previous cesarean section. Rupture of the uterus causes hemorrhage and shock. Without treatment it is fatal.

Avoidable Factors
These are factors causing or contributing to maternal death where there is departure from generally accepted standards of care. They can also be defined as factors which make a condition more likely to happen or more dangerous.
Intrapartum Management

Risk Factors

These should not be used to predict complications. The system of risk categorization or “the risk approach”, previously used for selecting women for specialized management is not useful, because evidence shows that many women categorized as “high risk” do not actually experience a complication, while many women categorized as “low risk” do. All pregnant women should therefore be considered “at risk” of developing complication.

Relevant points to find out from the woman, her family or the healthcare worker are:

- Her age
- Height, gait and any disability affecting the pelvis or lower limbs
- Medical history, in particular rickets, osteomalacia or pelvic injury
- Whether this is her first pregnancy and/or labor commenced at term
- Reason for any previous operative deliveries
- Previous stillbirth or early neonatal death and cause; if known
- Any complications during pregnancy
- Length of time in labor so far
- If partograph has been used, does cervical dilatation cross the alert or action lines

- Pattern of uterine action so far, e.g. contractions increased in frequency and duration, or stopped, etc.
- If membranes have ruptured
- If membranes have ruptured, how long ago did they rupture and is there any meconium-staining or foul smell?

CLINICAL PICTURE OF THE OBSTRUCTED LABOR

General Condition

In cases of obstructed labor there will be signs of physical and mental exhaustion. Some or all of the following signs and symptoms may also be observed:

- Maternal and/or fetal distress
- Dehydration and ketoacidosis (sunken eyes, thirsty, dry mouth, dry skin identified by skin pinch going back slowly)
- Fever (raised temperature)
- Abdominal pain which may be continuous
- Shock, rapid, weak pulse (100 per minute or more), diminished urinary output, cold clammy skin, pallor, low blood pressure (systolic less than 90 mm Hg), rapid respiratory rate (30 per minute or more), anxiousness, confusion or unconsciousness. Shock may be due to a ruptured uterus or sepsis.
Diagnosis of unsatisfactory progress of labor, abnormal labor patterns, diagnostic criteria and methods of treatment are shown in Tables 1 and 2.

Figures 3A and B show formation of the birth canal at the end of pregnancy and during the second stage of labor.

Abdominal Examination

Signs of obstructed labor that may be revealed by an abdominal examination are:

- The widest diameter of the fetal head can be felt above the pelvic brim because it is unable to descend; a large caput succedaneum may be fixed in the pelvic brim and this can be misleading, but careful palpation should identify that the widest diameter of the head is still above the brim; if the uterus is tonic, it will be very difficult to palpate because it is continuously hard and very painful for the woman.
- Frequent, long and strong uterine contractions (although if a woman has been in labor for a long time, contractions may have stopped because of uterine exhaustion); they restart with renewed vigor.
- The uterus may have gone into tonic contraction (i.e. it is continuously hard) and sits tightly molded around the fetus.
- Bandl’s ring may be seen (Fig. 4).

- Bandl’s ring is the name given to the area between the upper and lower uterine segments when it becomes visible and/or palpable during labor. In the process of normal pregnancy and labor, this area is called a retraction ring. It should not normally be seen or felt on abdominal examination.

Intrapartum Management

Figs 3A and B: Diagrams of the birth canal (A) at the end of pregnancy and (B) during the second stage of labor, showing formation of the birth canal

Abbreviations: CR, contraction ring; Int, internal; Ext, external.

Source: Adapted from Williams, 1903

Fig. 4: Diagnosing obstructed labor

- Bandl’s ring is a late sign of obstructed labor. It can be seen as a depression across the abdomen at about the level of the umbilicus. Above this is the grossly thickened, retracted upper uterine segment. Below the Bandl’s ring is the distended, dangerously thinned lower uterine segment. The lower abdomen can be further distended by a full bladder and gas in the intestines.

- Fetal heart may not be heard in severe cases of obstructed labor because the fetus dies from anoxia.

Vaginal Examination

The signs of obstruction that must be looked for are as follows:

- Foul-smelling meconium draining
- Amniotic fluid already drained away
- Catheterization will produce concentrated urine which may contain meconium or blood
- Vaginal examination:
  - Edema of the vulva, especially if the woman has been pushing for a long time
  - Vagina hot and dry because of dehydration
  - Edema of the cervix
  - Incomplete dilatation of the cervix (may be fully dilated in case of outlet obstruction)
  - A large caput succedaneum can be felt
  - The cause of the obstruction, e.g. excessively molded head stuck in pelvis, shoulder, brow or posterior face presentation, prolapsed arm.

Partograph Recordings

Obstructed labor may also be revealed if the recordings on the partograph indicate:

Normal shape of the abdomen

Shape of the abdomen in obstructed labor

Bandl’s ring

Retracted upper uterine segment

Distended lower uterine segment

Fig. 4: Diagnosing obstructed labor
• A prolonged first or second stage of labor which is evident because cervical dilatation will cross first the alert line and then, if no action is taken, will cross the action line despite a history of strong uterine contractions.

**Symptoms and Signs of Ruptured Uterus**

Ruptured uterus is common in multiparas but rare in nulliparas.

*Warning signs:* Bandl’s ring and tenderness of the lower segment of the uterus

Suspect rupture of the uterus if the following signs and symptoms are present:

- Shock
- Abdominal distension/free fluid
- Abdominal uterine contour
- Tender abdomen
- Easily palpable fetal parts
- Absent fetal movements and fetal heart sounds
- Rapid maternal pulse

Diagnosis could be more difficult, if rupture is incomplete or the tear is small. In this case, the fetus will remain at least partially in the uterus and signs of shock in the mother are delayed until after delivery because the pressure of the fetus prevents bleeding to some extent. Symptoms in this case could be initially very slight, and labor may even continue. Suspect rupture if the fetus suddenly becomes distressed and the mother’s pulse starts rising.

**MANAGEMENT**

A good prenatal care, risk screening and early referral can minimize the problems of obstructed labor. But suboptimal healthcare infrastructure is responsible for the appealingly high maternal mortality and morbidity in managing obstructed labor at rural areas in India. The delay in getting the proper care to the pregnant females with obstructed labor can better be understood by the three delay model system (Flow charts 1 and 2).

The first two delays relate directly to issue of access to care, encompassing factors in the family and the community including transportation. The third delay relates to factors in the health facility. The management of obstructed labor can be strengthened in the community by promoting basic emergency obstetric care at primary health centers and district hospitals. Care of patients with obstructed labor patients can be discussed according to management at various health centers.

**Six Steps to Providing Effective Management**

1. Identify the problem
2. Decide on the aim of management
3. Select the best management
4. Provide management, determining priorities
5. Evaluate the outcome
6. Provide further management, if necessary. This may include referral.

Stress the importance of working quickly and according to priorities so that urgent things are done first.

**Rehydrate the Patient**

* Aim: To maintain normal plasma volume and prevent or treat dehydration and ketosis

- Put up an intravenous (IV) infusion. Use a large needle (No. 18) or cannula. The infusion rates for IV fluids are shown in Table 3.
- If the woman is shocked, give normal saline or Ringer’s lactate. Run in 1 liter as quickly as possible, then repeat 1 liter every 20 minutes until the pulse slows to less than 90 beats per minute, systolic blood pressure is 100 mm Hg or higher. However, if breathing problems develop, reduce to 1 liter in 4–6 hours.
- If the woman is not in a shock but is dehydrated and ketotic, give 1 liter rapidly and repeat if still dehydrated and ketotic. Then reduce to 1 liter in 4–6 hours.
- Keep an accurate record of all intravenous fluids infused, and urinary output.

**Give Antibiotics**

If there are signs of infection, or the membranes have been ruptured for 18 hours or more, or the period of gestation is 37 weeks or less, give antibiotics as follows:

- Ampicillin 2 g every 6 hours, and
- Gentamicin 5 mg/body weight IV every 24 hours

If the woman is delivered by cesarean section, continue antibiotics and give metronidazole 500 mg IV every 8 hours until the woman is fever-free for 48 hours.

**Give Supportive Care**

The woman’s birth companion should be encouraged to stay with her to provide comfort and support. Staff should explain all procedures to the woman, seek her permission, discuss results with her, listen and be sensitive to her feelings.

**Deliver the Baby**

The doctor will assess the woman and her progress in labor and decide on the mode of delivery.

**Cephalopelvic Disproportion**

- If cephalopelvic disproportion is confirmed and fetus is alive, delivery should be by cesarean section.

**Obstruction**

- If the fetus is alive, the cervix is fully dilated and the head is at 0 station or below, deliver by vacuum extraction.
Flow chart 1A: Management plan of obstructed labor

- **Is there an indication for referral?**
  - Yes: First stage → Yes: Transport available → Yes: Refer to hospital
  - No: Manage according to local policy and protocols

- **Signs of fetal distress, or cord prolapse, or breech**
  - Yes: Manage according to local policy and protocols
  - No: First stage: Not delivered after 12 hours in labor

  - **First stage: Not delivered after 12 hours in labor**
    - No: Not delivered after 12 hours in labor
    - Yes: Strong contractions, or signs of obstructed labor. Cervical dilatation crossed alert line and reached action line on partograph
      - No: Second stage: Prolonged over 2 hours
      - Yes: Transport available

  - **Second stage: Prolonged over 2 hours**
    - No: Ensure bladder is empty. If no fetal or maternal distress, encourage the woman to adopt an upright position
    - Yes: Monitor descent of the fetus and observe fetal and maternal conditions closely
      - No: If no progress within 1 hour, arrange urgent referral, unless vacuum extraction
      - Yes: IV fluids because may have general anesthesia

- **Vacuum extractor available and midwife knows how to use it**
  - No: IV fluids
  - Yes: Attempt vacuum extraction, if head low in pelvis and cervix fully dilated
    - No: Baby delivery
    - Yes: Normal aftercare

- **Transport available?**
  - Yes: IV fluids, Analgesia, Antibiotics, if fever or membranes ruptured for 18 hours
    - Refer to hospital with midwife and delivery package
  - No: IV fluids, Antibiotics in fever or ruptured membranes in case of 18 hours or more of labor
    - Refer to facility with cesarean section
Management of Obstructed Labor at a Referral Center

If the fetus is alive and the cervix is fully dilated and there is evidence of indication for symphysiotomy for relatively minor obstruction (if cesarean section is not possible) and the fetal head is at -2 station, then delivery should be by symphysiotomy and vacuum extraction. Symphysiotomy is rarely performed at clinical centers. If the fetus is alive but the cervix is not fully dilated or if the fetal head is too high for vacuum extraction, referral should be made immediately for delivery by cesarean section.

If the fetus is dead:
- Delivery should be by craniotomy or other destructive procedures
- If this is not possible, delivery should be by cesarean section.

Thus the ultimate aim of such a condition is to expedite the delivery either vaginally or by cesarean section. This depends on the viability of fetus (Flow chart 3) and pelvic conditions. Forceps or vacuum is applied in cephalic presentation when head is low down and there are borderline pelvic outlet contractions. Destructive surgeries should be promoted at higher centers by trained professionals. The incidence of destructive surgery in our country is 10–25%.

Cesarean section is the preferred method. Hyperthermia, dehydration, electrolyte imbalance, sepsis and anemia can pose problems for anesthesia. Surgical interventions by abdominal route may at times lead to morbid conditions. Trauma to the bladder is very common with inexperienced hands, when the abdomen is opened because the bladder is high up and distended. The lower uterine segment is severely stretched out and hematoma can be seen in lower segment or there can be rupture of lower uterine segment.
Intrapartum Management

If performing a cesarean, the lower uterine incision should be given slightly higher up as there are high chances of extension of incision line vertically down or laterally while extracting the baby as the presenting part is deeply impacted in obstetric labor.

Since the lower uterine segment is very vascular any extension of incision laterally or downward can cause torrential bleeding. Difficulties in extracting out fetus due to drained out liquor and over molded uterus can necessitate inverted T-shaped incision in lower uterine segment or obstetricians may need to do classical cesarean in multigravidas in badly impacted obstructed labor. Atonic PPH can be lethal and may require cesarean hysterectomy or iliac vessels ligation. In case of rupture of uterus, cesarean hysterectomy is to be performed. In severely infected patients, it is mandatory to put abdominal drainage tube to prevent collection of infected fluid in abdominal cavity following surgical procedure. Complications while conducting vaginal delivery are much more difficult to manage. Vacuum extraction is always a better option than forceps application. Application of forceps in edematous and vascular vaginal tissue can be very traumatic. During delivery of the fetus vaginally, there can be extension of episiotomy upward in fornices which can cause severe hemorrhage and is also difficult to repair. At times, it can extend up to broad ligament. Fetal injuries particularly intracranial hemorrhage to the fetus can be fatal. There can be traumatic injuries to fetus. The maternal mortality is 8–12% following cesarean section as compared to 0–2% after embryotomy and vaginal delivery.

Postpartum care of the patient is equally important in order to minimize puerperal complications. Strict watch on vitals and PPH in labor room for 48 hours, broad spectrum antibiotics, indwelling catheterization for 7–10 days, suppression of breast milk if fetal demise, blood transfusion, postpartum contraception and future pregnancy counseling are some of the essential components of peripheral care. Even with the management under expert hands, maternal and fetal complications cannot be ignored.

COMPLICATIONS

Maternal Complications

- Genital tract trauma and rupture of uterus
- Postpartum hemorrhage
- Pulmonary embolism
- Puerperal infection
- Septicemia and shock
- Subinvolution of uterus
- Delayed healing of wounds
- Urinary fistulae (0.5–1%)
- Obstetric palsies

In general, the formula to figure out any IV infusion rate is as follows:

Amount of fluid given (cc) _____________________________________________

Time for infusion to occur (minutes)

In order to convert the time period from hours to minutes, multiply the number of hours by 60. This will give the number of minutes over which the IV fluids are to be given.

In spite of the best management facilities at tertiary centers, maternal and fetal morbidity in obstructed labor is a challenge to the obstetricians. Worldwide norms of various health agencies promote training of dais, provision of emergency obstetric care at periphery, supply of delivery kits to and upgrading of PHCs and subcenters and transport facilities. Risks that women face in bringing life into the world are not mere misfortunes or unavoidable natural disadvantages but this injustice to the females health in the society must remedy through its political, health and legal system mainly by promoting adolescent education, community education, antenatal and interval care and genuine commitment by the community, professionals and the government. If all the recommended norms of various family welfare programs are fulfilled, perhaps we will not have an obstructed labor and even if we have one, we would be in a better position to manage such condition from a grass root level in future obstetric era.9

REFERENCES
INTRODUCTION

Instrumental vaginal delivery refers to a delivery in which the operator uses forceps or a vacuum device to assist the mother in transitioning the fetus to extraterine life. Either instrument is applied to the fetal head and then the operator uses traction to extract the fetus, typically during a contraction while the mother is pushing.

Initially instrumental deliveries were performed to extract fetuses from parturients who were at high risk of maternal mortality due to prolonged and/or obstructed labor. In these cases, saving the mother's life took precedence over possible harm to the fetus. The focus of these procedures has changed as a result of modern obstetrical practices that have drastically reduced the risk of intrapartum maternal mortality and major morbidity. Decisions regarding use of instrumental delivery are now based primarily upon the fetal/neonatal impact of these procedures and are weighed against the alternative options of cesarean birth, prolonging the second stage, and second stage augmentation of contractions with oxytocin.

HISTORICAL ASPECT

The historical aspect of forceps is quite fascinating. The development of obstetrics forceps dates from the innovation made by one of the members of the Chamberlen family around 1600 AD. It was kept as a family secret for more than 100 years. Introduction of pelvic curve of the forceps is attributed to Levret in Paris, during the first half of the eighteenth century. It was Smellie who first used the forceps in aftercoming head of the breech delivery.

In 1849, Sir James Young Simpson in Edinburgh was the first to produce an apparatus, which delivered a baby's head with the aid of suction. Malmstrom’s modern vacuum extractor differs only in detail and refinement from Simpson’s suction and traction mechanism.

INCIDENCE

Approximately 6% of all births in the United States are accomplished via an instrumental vaginal approach. Exact Indian data is not available but from various studies current prevalence rate is 10–20%. The overall rate of instrumental vaginal delivery has been diminishing, but the proportion of instrumental vaginal deliveries conducted by vacuum-assisted births has been increasing and is twice the rate of forceps-assisted births.

INDICATIONS

According to American Congress of Obstetricians and Gynecologists (ACOG) and Royal College of Obstetricians and Gynaecologists (RCOG) guidelines for instrumental vaginal delivery, no indication is absolute. The following indications are currently used:

- Prolonged second stage of labor. In nulliparous women, this is defined as lack of continuing progress for 3 hours with regional anesthesia or 2 hours without anesthesia. In multiparous women, it refers to lack of continuing progress for 2 hours with regional anesthesia or 1 hour without anesthesia.
- Suspicion of immediate or potential fetal compromise (e.g. non-reassuring fetal heart rate pattern, abruption) where expeditious vaginal delivery can be readily accomplished.
- Shortening the second stage of labor for maternal benefit (e.g. maternal cardiac disease, some neurologic conditions, exhaustion).
In the past, shortening the second stage was an acceptable option, independent of any specific maternal or fetal indications, because early studies suggested that the risks of fetal and maternal morbidity were higher when the second stage of labor exceeded two hours. The evidence does not support this practice.

The ability of fetal heart rate monitoring to identify the fetus not tolerating labor has made the arbitrary termination of labor because of any elapsed period of time unwarranted. Furthermore, maternal risks of a prolonged second stage (e.g. pelvic floor injury, postpartum hemorrhage) appear to be more related to instrumental intervention than the length of the second stage.

### PREREQUISITES

The operator should be an individual experienced in instrumental vaginal delivery. This individual should determine the following prerequisites prior to application of instruments.

- The cervix is fully dilated
- The membranes are ruptured
- The head is engaged.

Fetal presentation, position, lie and any asynclitism are known. The fetus must be in a vertex presentation (unless the purpose is to use forceps to assist in delivery of an aftercoming head). If fetal presentation or position is uncertain, use of ultrasound intrapartum can be helpful. In one study, digital examination incorrectly defined fetal head position in over 25% of cases about to undergo instrumental vaginal delivery. Large infants, extreme molding, extension of the fetal head, pelvic deformities and asynclitism may falsely suggest engagement of the vertex. In these cases, the leading bony part is at the ischial spines, although the biparietal diameter has not passed through the pelvic inlet. Ultrasound examination should be performed and is highly accurate.

- The fetal size has been estimated and clinical pelvimetry shows adequate mid and outlet pelvic dimensions, and no obstructions or contractures exist.
- Maternal anesthesia is satisfactory.
- The patient consents to the procedure. The risks of the procedure should be explained to the woman and documentation of the indication and maternal and fetal assessments should be made in the medical record.

The option of performing an immediate cesarean delivery should be possible if complications arise.

In addition, postdelivery, the pediatrician should be informed that the birth was attempted or assisted by vacuum or forceps.

### CONTRAINDICATIONS

Most contraindications to instrumental delivery are related to the potential for unacceptable fetal risks. Fetal prematurity is a relative contraindication. Other contraindications include known fetal demineralizing diseases (e.g. osteogenesis imperfecta), collagen disorders (e.g. Ehlers-Danlos syndrome), fetal bleeding diatheses (e.g. hemophilia, alloimmune thrombocytopenia), unengaged head, unknown fetal position and suspected fetal-pelvic disproportion. A nonreassuring fetal heart rate pattern is not a contraindication to instrumental vaginal delivery.

In addition, vacuum devices should not be used to assist delivery prior to 34 weeks of gestation because of the risk of fetal intraventricular hemorrhage. Prior scalp sampling or multiple attempts at fetal scalp electrode placement are also relative contraindications to vacuum extraction since these procedures may increase the risk of cephalohematoma or external bleeding from the scalp wound. Contraindications to the use of forceps are listed in Table 1. In some of these conditions, vacuum can be used safely.

### Table 1: Contraindications to the use of forceps

- Absence of a proper indications
- Incompletely dilated cervix
- Marked cephalopelvic disproportion
- Unengaged fetal head
- Lack of experience on the part of the operator

### Minimum and Maximum Estimated Fetal Weight

There is no consensus regarding the minimum and maximum estimated fetal weights that should preclude instrumental vaginal delivery.

**Upper threshold:** Instrumental delivery of the macrosomic infant may be associated with an increased risk of injury. A trial of labor and careful use of forceps or vacuum extraction are acceptable for most fetuses suspected to be macrosomic. Under these circumstances, the obstetrician should be aware of the risk of shoulder dystocia, especially when the second stage of labor is prolonged.

**Lower threshold:** As discussed above, vacuum devices should not be used to assist delivery prior to 34 weeks of gestation (mean birth weight 2,500 g because of increased risks of fetal intraventricular hemorrhage in premature infants. Premie sized forceps have been used on fetuses as small as 1,000 g.

There are no prospective randomized trials examining the impact of prophylactic low forceps delivery in low birth weight infants.

Immediate and later head ultrasound examinations of 230 infants with estimated fetal weights of less than 1,750 g observed that the overall incidence of cerebral hemorrhage was the same after vaginal and cesarean deliveries (41% and 44%, respectively). However, lower incidence of hemorrhage was noted after vaginal delivery with forceps (17%).

In contrast, several other studies have suggested an increased risk of intraventricular hemorrhage with prophylactic low forceps.
In summary, the evidence does not clearly identify a superior mode of delivery in cephalic presenting low birth weight infants. Reassuringly, larger trials do not demonstrate any increase in neurologic injury with the use of low forceps in low birth weight infants and a role for low forceps in clinically indicated situations would appear reasonable in this population. Two forceps are available which are smaller in dimension than standard forceps and are intended for use in the low birth weight or very low birth weight populations. “Baby” Elliot and “baby” Simpson forceps are among these instruments. Unfortunately, we were unable to identify any published studies or manufacturer guidelines regarding the estimated fetal weights or gestational ages at which these instruments might be most useful.

**TRIAL OF INSTRUMENTAL DELIVERY**

An instrumental vaginal delivery should only be considered when the likelihood of success is high because there may be a higher rate of birth trauma after failed attempts at instrumental delivery (although one can never be certain of a successful outcome). In one study, the rates of subdural or cerebral hemorrhage, facial nerve injury, convulsions, central nervous system depression and mechanical ventilation were higher in infants delivered by cesarean birth after a failed instrumental delivery than in those delivered by cesarean with no prior attempt at instrumental vaginal delivery. However, other studies have not shown adverse effects from failed instrumental vaginal delivery as long as cesarean delivery followed promptly.

**CHOICE OF ANESTHESIA**

Local anesthesia is preferred than general anesthesia as maternal voluntary bearing down efforts are present.
- Perineal infiltration
- Pudendal nerve block
- Epidural anesthesia
- Spinal anesthesia
- General anesthesia.

**CLASSIFICATION OF FORCEPS DELIVERIES**

The ACOG redefined the classification of forceps delivery in 1988 to better reflect the degree of difficulty and attendant risk (e.g. lower fetal station and smaller degrees of head rotation are associated with reduced maternal and fetal injury). The criteria for different types of forceps deliveries are as follows.

**Outlet forceps:** The application of forceps when the scalp is visible at the introitus without separating the labia, the fetal skull has reached the pelvic floor, the sagittal suture is in anteroposterior diameter or a right or left occiput anterior or posterior position, the fetal head is at or on the perineum, rotation does not exceed 45°.

**Low forceps:** The application of forceps when the leading point of the fetal skull is 2 cm or more beyond the ischial spines (at least +2 cm station), but not on the pelvic floor. Low forceps have two subdivisions: (1) rotation is 45° or less (left or right occiput anterior to occiput anterior, or left or right occiput posterior to occiput posterior) and (2) rotation more than 45°.

**Midforceps:** The application of forceps when the head is engaged, but the leading point of the skull is higher than +2 cm station.

**Rotational forceps (Kielland forceps) (Figs 1 and 2):** The pelvic curve is almost nonexistent, making the instrument ideal for rotating the fetal head. Rotation can be accomplished simply by twisting the closed handle instead of sweeping them through a wide arc, as is necessary when using forceps with a deep pelvic curve. The sliding lock makes the locking of blades easier. Delivery can be accomplished with the same instrument: no reapplication is needed.
Under very unusual circumstances, such as the sudden onset of severe fetal or maternal compromise, application of forceps above +2 cm station may be attempted while simultaneously initiating preparations for a cesarean delivery in the event the forceps maneuver is unsuccessful. Under no circumstances, however, forceps should be applied to an unengaged presenting part or when the cervix is not completely dilated.

**Choice of Instrument**

The choice of instrument is determined by level of training with the various forceps and vacuum equipment. Factors that might influence choice are the availability of the instrument, the degree of maternal anesthesia, and knowledge of the risks and benefits associated with each instrument. In general, vacuum devices are easier to apply, place less force on the fetal head, require less maternal anesthesia, and do not affect the diameter of the fetal head compared to forceps. By comparison, the advantages of forceps are that they are unlikely to detach from the head, can be sized to a premature cranium, may be used for a rotation, and do not aggravate bleeding from scalp lacerations.

**Vacuum (Figs 3 and 4):** Metal or rigid cups were more suitable for occiput posterior, transverse and difficult occiput anterior deliveries, whereas the soft cup was appropriate for uncomplicated deliveries.

**Obstetrics Forceps (Fig. 5)**

In general, the instrument selected should have cephalic and pelvic curves appropriate to the size and shape of the fetal head, maternal pelvis and planned procedure. Midpelvic deliveries are facilitated by an instrument that can be used with a traction handle (e.g. Bill’s axis-traction handle) and a sliding lock is helpful when there is asynclitism. Simpson type forceps tend to fit a long molded head, Elliot or Tucker-McLane type forceps are better suited to a round unmolded head and Kielland forceps are useful for rotations because of their minimal pelvic curve and sliding lock.

**APPLICATION (FIG. 6)**

**Forceps:** Appropriately, applied forceps grasp the occiput anterior fetal head such that:
- The long axis of the blades corresponds to the occipito-mental diameter
- The tips of the blades lie over the cheeks
- The blades are equidistant from the sagittal suture, which should bisect a horizontal plane through the shanks
- The posterior fontanelle should be one finger breadth anterior to this plane
- Fenestrated blades should admit no more than one finger breadth between the heel of the fenestration and the fetal head
- No maternal tissue has been grasped.

**Traction (Figs 4 and 7):** Traction with either forceps or vacuum should be steady (not rocking) and in the line of the birth canal. Traction should be exerted with each contraction and in conjunction with maternal expulsive efforts. In most cases, progress is noted with the first or second pull and delivery occurs by the third or fourth pull. The procedure should be abandoned if descent does not occur with appropriate application and traction. The negative pressure created in vacuum is 0.7–0.8 kg/cm². This takes 8–10 minutes. The total extraction time may be 15 minutes, or 5–10 tractions during uterine contraction. If the cervix is not fully dilated, it may take longer. The upper time limit is 30 minutes to prevent damage to the baby.

An observational study of 119 vacuum-assisted deliveries using a vacuum device with a traction force indicator found that 80% of extractions occurred with 11.5 kg (25 lbs) or less
traction and 20% with greater than 11.5 kg traction. Only two deliveries had greater than 13.5 kg (30 lbs). Neonatal scalp abrasion and cephalhematoma were more common in infants born with traction greater than 11.5 kg.

**Figs 4A to C:** Vacuum extractor. (A) Traction outward and posteriorly; (B) Traction outward and horizontally; (C) Traction outward and anteriorly

Multiple Trials of Instrumental Delivery

The ACOG has suggested that multiple attempts at instrumental vaginal delivery using different instruments (vacuum, different types of forceps) be avoided due to the greater potential for maternal and/or fetal injury. In one large study, the incidence of subdural or cerebral hemorrhage in infants delivered by vacuum and forceps, vacuum alone, or forceps alone was approximately 21, 10, and 8, per 10,000 births respectively.
All hematomas had resolved without clinical sequelae when reevaluated 4 weeks later.

RISKS

The risks associated with instrumental vaginal delivery need to be evaluated with respect to appropriate control groups and reasonable alternative procedures. This was illustrated by a study assessing the incidence of intracranial hemorrhage related to labor and mode of delivery in 583,340 singleton infants born to nulliparous women in California. The rate of subdural or cerebral hemorrhage associated with vacuum extraction was equivalent to that associated with forceps use or cesarean delivery during labor, but higher than after spontaneous delivery or a cesarean delivery performed prior to labor. This suggests that abnormal labor was the major risk factor for this complication, rather than mode of delivery.

Forceps versus Vacuum Extraction

Comparative data on the risks of instrumental delivery are illustrated by the following examples from large studies:

- A meta-analysis of 10 trials comparing vacuum to forceps delivery found vacuum deliveries were associated with less maternal soft tissue trauma (OR 0.41, 95% CI 0.33–0.50), required less general and regional anesthesia, and resulted in fewer cesarean deliveries. However, use of a vacuum device was less likely to result in successful vaginal delivery than forceps. The lower cesarean delivery rate after attempted vacuum extraction was likely due to follow-up trial of forceps, whereas failed forceps typically resulted in a cesarean delivery.

Neonates delivered by vacuum extraction had more neonatal cephalohematoma (OR 2.38) and retinal hemorrhages (OR 1.99) than those delivered by forceps. These problems generally are not associated with long-term complications.

Vacuum-assisted deliveries were associated with significantly lower rates of birth injury, seizures and assisted ventilation than forceps-assisted deliveries after adjustment for confounders; neonatal death rates were equivalent.

VENTOUSE

The term ventouse is derived from the French word meaning “soft cup”. Theoretical advantages of vacuum extractor compared with forceps includes:

- Avoidance of insertion of space occupying steel blades within the vagina
- No requirement for precise positioning over the fetal head
- Less maternal trauma
- Less intracranial pressure during traction

Technique

Proper cup placement is the most important determinant of success in vacuum extraction. The center of cup should be placed over the sagittal suture and about 3 cm in front of the posterior fontanel toward the face (Flow chart 1).

Complications

- Scalp lacerations and bruising
- Subgaleal hematoma
- Cephalohematoma
- Enhanced hemorrhage
- Neonatal jaundice
- Subconjunctival hemorrhage
- Clavicular fracture
- Shoulder dystocia
- Injury
Recomendations Regarding Vacuum Delivery

- The classification of vacuum deliveries should be the same as that used for forceps deliveries (including station).
- The same indications and contraindications used for forceps deliveries should be applied to vacuum-assisted deliveries.
- The vacuum should not be applied to an unengaged vertex, i.e. above 0 station.
- The individual performing or supervising the procedure should be an experienced operator.
- The operator should be willing to abandon the procedure if it does not proceed easier or if cup dislodges more than three times.

Risks Related to Instrumental Delivery

Maternal Short-term Risks

Maternal risks from instrumental delivery include pain at delivery, perineal pain at 24 hours, lower genital tract lacerations and hematomas, urinary retention, anemia and rehospitalization. These complications are higher with both vacuum and forceps compared to spontaneous delivery. The greater degree of perineal trauma associated with instrumental delivery was illustrated by a retrospective review of 50,210 vaginal deliveries. The rates of third and fourth degree lacerations for spontaneous vaginal delivery, vacuum extraction and forceps delivery is 1.7%, 9.3% and 19.2%, respectively.

Maternal morbidity related to different types of instrumental delivery was illustrated by a randomized study comparing deliveries by forceps and two different types of vacuum cup. There was at least one significant adverse maternal outcome (e.g. periurethral/labial laceration, vaginal laceration, third or fourth degree laceration, vulvar or vaginal hematomas, or cervical lacerations) in 48% of forceps, 36% of silastic vacuum extractor and 22% of Mityvac vacuum extractor deliveries.

Maternal trauma is greatest with rotational and midforceps operations. Direct bladder injury and ureteral lacerations/transsections have been reported in such cases.

It is customary to give episiotomy in instrumental deliveries. In multiparous patient, episiotomy can be safely avoided.

Fetal position also has an impact. For occiput posterior position, the rate of anal sphincter and rectal injury with forceps and vacuum is higher than the rate with occiput anterior position (54% for forceps and 27% for vacuum).

Although spontaneous vaginal delivery is less traumatic for the mother than instrumental vaginal delivery, the latter is associated with less short-term maternal morbidity than cesarean delivery.

Maternal Long-term Risks

Long-term maternal sequelae from instrumental delivery are primarily related to disturbances in urinary and anal function, such as urinary incontinence, fecal incontinence, pelvic organ prolapse and, occasionally, fistula formation. The range of these complications vary from center to center.

- In a new study, 4% developed new fecal incontinence postpartum. Forceps and vacuum delivery were the only independent risk factors identified for this complication.
- A prospective series of 159 women who underwent endosonography after spontaneous, forceps and cesarean delivery found sphincter injury in 8.7%, 83%, and 0% respectively.
- A study of 149 women before and 9 weeks after delivery reported stress urinary incontinence was more common after instrumental delivery compared to spontaneous delivery (34% versus 21%).
- Any increase in risk of long-term maternal morbidity from different types of instrumental vaginal delivery cannot be accurately quantitated and compared because of the lack of adequate randomized studies with appropriate control groups.

Recurrence Risk

Mode of delivery after a previous instrumental vaginal delivery has not been extensively evaluated. A 3-year follow-up study that surveyed women who had undergone a successful term instrumental vaginal delivery in the second stage reported 42 of 54 (78%) women achieved vaginal delivery in the subsequent pregnancy and 3 of the 54 (5.6%) women had another instrumental delivery.

Fetal Short-term Risks

The short-term risks to the fetus from instrumental vaginal delivery are usually caused by head compression and traction on the fetal intracranial structures, face and scalp.

- Vacuum-assisted deliveries: The incidence of serious complications with vacuum extraction is approximately 5%. Torsion and traction of the vacuum cup can cause fetal scalp abrasions and lacerations, separation of the scalp from underlying structures leading to cephalohematoma, subgaleal hematoma (26 to 45 per 1,000 vacuum deliveries; Figs 8A and B) intracranial hemorrhage, hyperbilirubinemia and retinal hemorrhage. These hemorrhages typically resolve without sequelae within 4 weeks of birth. A study of 913 term newborns who were successfully delivered using a vacuum device and who had a skull X-ray and head ultrasound reported skull fracture in 46 (5%). All of the fractures were linear (nondepressed) and no infant was symptomatic. The scalp is sucked into the cup and an artificial caput succedaneum (Chignon) is produced. The chignon usually disappears within few hours. Other injuries which can occur in fetal scalp are shown in Figures 8A and B.
Death from intracranial hemorrhage has been reported. Shoulder dystocia also appears to be more common with vacuum-assisted than forceps deliveries.

- **Forceps-assisted deliveries**: Short-term complications resulting from forceps deliveries include skin markings and lacerations, external ocular trauma, subgaleal hematomas, hyperbilirubinemia, retinal hemorrhage, lipoid necrosis, nerve injury, skull fractures and death. Facial palsies and depressed skull fractures, in particular, are more common with use of forceps than vacuum devices; both complications can also occur after a non-instrumental delivery.

**Fetal Long-term Risks**

Acute fetal injuries with potential long-term sequelae include intracranial hemorrhage (subdural, subarachnoid, intraventricular and/or intraparenchymal hemorrhage) and neuromuscular injury; however, these sequelae are rare.

Developmental outcome appears to be equivalent for both forceps-assisted and vacuum-assisted births. There was no difference in child development between the groups after 5 years of follow-up.

**Specific Points**

**Floating Forceps**

The whole fetal head is above the pelvic brim. This procedure is not performed today, having been superseded by cesarean section.

In the case of a brim or a high cavity application, the only alternative to axis-traction is the use of Pajot’s maneuver (Fig. 9), in which the same resultant effect is attempted by pressing downwards on the shanks of the blades at the same time as traction is exerted. This maneuver incidentally was introduced before the discovery of the principle of axis-traction and is far cruder. Nowadays the importance of axis-traction is dwindling, as the high forceps operation is rarely performed in sound obstetrics practice.

**Midpelvic Arrest: Forceps or Cesarean Section**

Current obstetrics practice is likely to discourage the use of midforceps for delivery of patients whose second stage of labor is prolonged. Some maintain that the danger of both obvious and hidden damage is too great, and that this procedure must be replaced by cesarean section.

Providing there is no cephalopelvic disproportion, midforceps when performed properly by competent hands and on correct indications need not be mutilating to the mother nor impose undue hazards on the fetus. When the head is engaged deeply with the biparietal diameter at the level of ischial spines and the station of +2, midforceps is the procedure of choice, as specially when uterine inertia or maternal fatigue results in arrest in the second stage. The midforceps operation is an important part of obstetrics.

**Failed Forceps or Catastrophic Success**

An attempt to deliver the baby by forceps may fail completely or it may produce a damage or dead baby and leave the mother with a lacerated pelvis. Pitfalls that contribute to making a wrong decision include:

- Misunderstanding the significance and the relationship of station and the level of the biparietal diameter
- Unrecognized disproportion
- Misdiagnosis of station
  - Rectal examination may be inaccurate and unreliable
  - Caput succedaneum
  -Molding
- Misdiagnosis of position, cervical dilatation, inefficient uterine action
- A constriction ring of myometrial spasm that grips the fetus tightly and prevents decent
- Premature interference
- Indecision and stubbornness.
Trial Forceps

The principle of trial forceps postulates that after successful application has been achieved, gentle traction is made. Should the head come down easily the operation is continued and the baby is delivered. If, on the other hand, the operator feels that an undue amount of force would be required to extract the head, the forceps are removed and cesarean section is carried out.

Forceps to Aftercoming Head (Figs 10A to C)

Piper forceps or divergent Laufe forceps may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps should not be applied to the aftercoming head until it has been brought into the pelvic cavity by gentle traction, combined with suprapubic pressure and is engaged. Suspension of the body of the fetus in a towel effectively holds the fetus and helps keep the arms out of the way.

SUMMARY AND RECOMMENDATIONS

There is inadequate evidence upon which to base a recommendation for use of either vacuum or forceps for all circumstances when instrumental vaginal delivery is attempted. We believe current evidence supports use of vacuum to minimize maternal morbidity when the gestational age is greater than 34 weeks and the likelihood of success is very high. When success is uncertain, primary use of forceps may reduce the morbidity that has been
associated with combined sequential instrumental delivery. In addition:

- Non-medically indicated shortening of the second stage is not an indication for instrumental vaginal delivery
- Vacuum-assisted deliveries are associated with an increase in neonatal cephalohematomata and retinal hemorrhage. These complications generally resolve without sequelae
- Forceps-assisted deliveries cause significantly more acute maternal injury and fetal facial nerve injury than vacuum-assisted instrumental deliveries or spontaneous deliveries
- Vacuum devices should not be used prior to 34 weeks of gestation or longer than 20 minutes because of the increased risk of intraventricular hemorrhage
- There was no significant difference in results of cognitive testing when 5-year-old children delivered by instrumental vaginal delivery were compared to children delivered by spontaneous vaginal delivery.

An age-old dictum holds true even today! "By skill and not by force".

**BIBLIOGRAPHY**

CHAPTER 36

Modern Management of Breech Presentation

INTRODUCTION

Breech presentation accounts for 3–4% of term singleton pregnancies. At 28 weeks of gestation, 20% of fetuses present as breech and in the 29 to 32 weeks of gestation group, 14% of fetuses are in breech presentation. As term approaches, the incidence of breech presentation steadily decreases as in most cases, the fetus converts to cephalic presentation by 34 weeks of gestation (spontaneous version). Fifteen percent of babies presenting by breech at the onset of labor are preterm, three times the overall rate of preterm labor.

Any condition of the uterus, placenta, umbilical cord, amniotic fluid, fetus or pelvis which interferes with spontaneous version results in a persistent breech presentation. Any neuromuscular dysfunction in the fetus prevents the baby from kicking itself into the head-down position. Breech presentation, but not breech birth, has a predictive relationship to cerebral palsy, meaning thereby that central nervous system damage precedes labor and causes the malpresentation or persistent breech. Breech presentation may be caused by antecedent neurologic abnormalities that are not amenable to prevention by labor or delivery interventions.

Antepartum Risk Factors

The various antepartum factors associated with a persistent breech are:
- Prematurity
- Multiparity
- Multiple pregnancy
- Uterus—Müllerian anomalies, fibroids
- Contracted pelvis
- Placenta previa, placental implantation in cornual-fundal region
- Short umbilical cord
- Oligohydramnios, polyhydramnios
- Fetus—growth retardation
- Congenital anomalies like neural tube defects.

Incidence of anomalous fetus in breech is twice that seen in cephalic presentations, 6.3% versus 2.4%.

- Diabetes mellitus
- Smoking.

It is possible that smoking results in altered neuromuscular coordination and hence inability of the fetus to undergo spontaneous version.

In many cases, no reason or association for the breech presentation is found and, by exclusion, the cause is attributed to chance.

Intrapartum Factors in Breech

- The uneven fit of the breech to the pelvis predisposes to early rupture of membranes and cord prolapse. The incidence of cord prolapse in breech presentation is 4–5% and is higher in footling breech.
- Preterm, prelabor rupture of membranes.
- Dysfunctional labor—Breech is a poor dilator of the cervix compared to the fetal head, hence, labor, descent and cervical dilatation may take longer.
- Obstructed labor, entrapment of after-coming head of breech, nuchal arms are peculiar to breech births.
All the above antenatal risk factors, along with intrapartum events, place the breech fetus in a “high risk pregnancy and labor group”.

The various modalities of managing a term breech fetus are:
- External cephalic version and delivery as vertex
- Elective cesarean
- Trial of breech (selective cesarean).

**Modes to Promote Version**

- External cephalic version (ECV)
- Moxibustion is a procedure in Chinese traditional medicine wherein combustible herbal material is placed atop acupuncture needles at acupoints. Stimulation of acupoint BL67, located besides the outer corner of the fifth toenail, for 1–2 weeks, promotes correction of breech presentation by increasing fetal activity.
- Hypnosis
- Acupuncture
- Knee-chest position with buttocks higher than the trunk for 15 minutes, every 2 hours of waking for 5 days
- Abduction of thighs with elevation of pelvis with breathing techniques.

**EXTERNAL CEPHALIC VERSION**

External cephalic version (ECV) refers to external, per- abdomen maneuvers by which breech presentation is changed to cephalic. The use of sonography, electronic fetal heart rate monitoring along with tocolysis results in ECV being a safe and effective procedure for the management of the term breech. All women at term with an uncomplicated pregnancy and breech presentation should be offered ECV. Incorporating ECV in clinical practice would result in reduction in breech births from 78% to 44% and a reduction in cesarean section rate from 29% to 15%. Factors that may modify the success of external cephalic version are presented in Table 1.

**Pre-requisites for External Cephalic Version**

1. Written, informed consent.
2. **Term breech:** Traditionally, ECV was performed at 32 weeks though the present trend is to perform ECV after 36 weeks. In a preterm breech, ECV is technically easier to perform due to a relatively large amniotic fluid pool and a small fetus, but it is not recommended for the following reasons:
   - The spontaneous cephalic version rate is 57% after 32 weeks and 25% after 36 weeks. This does not support the use of ECV with its attendant risks at lower gestational age. At term, the spontaneous version rate varies from 14% to 22% and there appears to exist a constant ratio of 3:1 between ECV success and spontaneous version rates.
   - The risk of preterm labor and rupture of membranes exists with preterm ECV. Also, in the event of fetal distress during preterm version, one may be forced to deliver a baby before term resulting in iatrogenic prematurity, an avoidable complication.
   - Spontaneous re-version to breech after ECV occurs in 1–4% cases at term and the incidence would be much higher if ECV is done in preterm fetuses.
   - Contraindications to ECV like growth restriction, preeclampsia and oligohydramnios may not be apparent till term.
3. Ultrasonography to confirm presentation and to rule out contraindications for ECV.
4. Contraindications ruled out, namely:
   - Compromised fetus—intrauterine growth restriction (IUGR), pregnancy-induced hypertension (PIH)
   - Nonreactive nonstress test (NST)
   - Oligohydramnios
   - Placenta previa
   - Multiple pregnancy
   - Any contraindication to labor or vaginal delivery
   - Any obstetric indication for cesarean

External cephalic version in a case of previous transverse lower segment cesarean has been found to result in no serious maternal or neonatal complications.

5. Preprocedure NST.
6. Fetal heart rate monitoring during ECV and intra-procedure ultrasound surveillance.
7. Provisions made for immediate delivery in the event of fetal distress during ECV.
8. Postprocedure NST.
9. Administration of anti-D immunoglobulin to Rh-negative women, undergoing ECV.
10. **Tocolysis:** Terbutaline 0.25 mg subcutaneously is useful in cases wherein the tone of the uterus was a cause of an unsuccessful ECV. In other cases, use of tocolytics did not demonstrate an increased incidence of successful version. Use of nitroglycerine spray as a tocolytic
for ECV was not found to be useful and was associated with significant side-effects in the form of headaches and symptomatic hypotension.

Complications of External Cephalic Version

- Transient fetal bradycardia occurs in 3–4% cases
- Placental separation
- Rupture of membranes
- Cord prolapse, cord entanglements
- Fetomaternal hemorrhage in 1.8% cases
- Fetal distress, fetal death.

Successful External Cephalic Version Factors

Successful external cephalic version depends on the following factors:

- Multiparity (lax abdominal wall and lower resting tone of the uterus)
- Nonfrank breech—extended legs of a frank breech have a splinting effect and decrease the maneuverability of the fetus
- Unengaged breech
- Adequate amniotic fluid pool
- Posterior placental implantation
- Repeat ECV at a later date after an unsuccessful attempt
- Transabdominal amnioinfusion of saline in oligohydramnios
- Fetal acoustic stimulation to shift the fetal spine to a lateral position in cases of midline spines.

Success of ECV varies from 48% to 93% in various studies. A failed version is associated with an 83% cesarean rate while the cesarean rate in version cases drops to 37%.

Egge et al. state that the outcome of labor following ECV is no different from that of a cephalic presentation and that there is no dystocia or dysfunctional labor requiring cesarean in ECV successful patients. On the other hand, Lau et al. quoted a cesarean rate of 16.9% in the ECV successful group (cesarean rate 2–2.5 times higher than the control group of non-ECV cephalic presentations) due to fetal distress and dystocia labor. They concluded that pregnancy and labor after successful ECV should be considered as high risk in view of higher chances of fetal distress and dystocia. It is possible that the breech presentation by itself, with its association with atypical neuromuscular function and predilection to abnormal fetal heart rate patterns due to central nervous system dysfunction results in intrapartum fetal distress and dystocia which may be interpreted incorrectly as acquired fetal jeopardy in labor. The Westin scoring system for selecting mode of delivery in breech is presented in Table 2.

Vagaries of a Vaginal Breech Birth

An irregular presenting part, namely the breech (compared to vertex), is a slow dilator of the cervix with resultant tardy progress of labor.

The largest and the least compressible fetal part, the head delivers last in a breech delivery with the risk of entrapment of the aftercoming head.

If all the parameters of pelvis are included, a score of 12 is safe for vaginal delivery. However, if any single score lies within the outlined box, or any two entries within the interrupted lines, Westin considered that LSCS was indicated irrespective of the total score. However, a lot of parameters in this system are based on pelvimetry other than clinical, which is not routinely done.
An irregular ill-fitting presenting part, the breech, contributes to premature rupture of membranes along with the risk of cord prolapse.

Sudden excessive pressure on the after-coming head of breech results in tentorial tears and intracranial hemorrhage as opposed to the slow gradual head moulding in vertex deliveries.

Patients with failed ECV can be offered a choice of “elective cesarean” versus “selective cesarean (trial of breech)

**Recommendations for Delivery (Cesarean)**

Cesarean delivery is commonly, but not exclusively, used in the following circumstances:
- A large fetus
- Any degree of contraction or unfavorable shape of the pelvis determined clinically or with computed tomography (CT) pelvimetry
- A hyperextended head
- When delivery is indicated in the absence of spontaneous labor
- Uterine dysfunction—some would use oxytocin augmentation
- Incomplete or foaling breech presentation
- An apparently healthy and viable preterm fetus with the mother in either active labor or in whom delivery is indicated
- Severe fetal-growth restriction
- Previous perinatal death or children suffering from birth trauma
- A request for sterilization
- Lack of an experienced operator.

**ELECTIVE CESAREAN**

Proponents of this policy vouch that all breech births must be by the abdominal route because of the concern for birth trauma and birth asphyxia with vaginal birth and unexpected arrest of fetal parts at delivery. Lee et al. concluded that primary cesarean births as against vaginal birth for breech are associated with significantly lower neonatal mortality for all birth weight groups. Krebs et al. conducted a register-based study and concluded that elective cesarean for the term breech gives improved perinatal outcome with respect to intrapartum and early neonatal deaths and Apgar scores.

A landmark multicentric randomized controlled study—“The Term Breech Trial”, comparing planned cesarean versus planned vaginal birth was conducted by Hannah et al. of the University of Toronto, Canada from 1997 to year 2000. A total of 2088 women were recruited from 121 centers of 26 countries. Of the women assigned planned cesarean, 90.4% delivered by cesarean and of the women assigned planned vaginal birth, 56.7% delivered vaginally. Perinatal mortality, neonatal mortality and serious neonatal morbidity were significantly lower for the planned cesarean group. There was no difference between the two groups in terms of maternal mortality or serious maternal morbidity. The study concludes that planned cesarean is better than planned vaginal birth for the term breech, the benefits being greater in countries having lower perinatal mortality rates.

The authors (Dr Vandana Walvekar and Dr Pratima Anjaria of the Nowrosjee Wadia Maternity Hospital, Mumbai, Maharashtra, India) were part of the Term Breech Trial team. Wadia Hospital was one of the three centers from India to have participated in this international study. The authors’ experience with respect to maternal and fetal outcome was similar to the final result of the trial.

**TRIAL OF BREECH (VAGINAL BREECH DELIVERY)**

Patient selection is done by the following criteria:
- Thirty-seven completed weeks of gestation (term)
- Frank or complete breech (buttocks below the feet)
- Estimated fetal weight between 1.5 kg and 3.5 kg. For fetuses weighing less than 1.5 kg, it is justifiable to perform a cesarean if the baby can be received in an intensive care unit wherein it has at least a 40% chance of an unhandicapped survival
- Well-flexed head
- No fetopelvic disproportion
- No contraindication for labor or vaginal birth
- No obstetric indication for cesarean
- No growth retardation with head-sparing effect
- Informed consent. The patient is counseled about the 20% rate of failed trial of breech and resultant emergency cesarean.

**Pre-requisites and Requirements for Conduct of a Trial of Breech**
- Strict inclusion criteria and ruling out contraindications to a vaginal breech birth
- Informed consent
- Availability of a skilled and trained obstetrician along with a neonatologist and anesthetist
- Partogram to detect tardy labor
- Resorting to cesarean in cases of failure of descent of breech or failure of cervical dilatation (an indication of fetopelvic disproportion)
- Oxytocin to augment labor in the absence of fetopelvic disproportion
- Avoid ARM till the breech distends the perineum
- In cases of spontaneous rupture of membranes, an immediate per vaginal examination is mandatory to rule out cord prolapse
- Lumbar epidural analgesia relieves pain and prevents involuntary bearing-down efforts prior to full dilatation, thus preventing the occurrence of the breech slipping
through a partially dilated cervix with arrest of the aftercoming head
• Delivery in the operation theater by “assisted breech delivery” with an adequate and generous episiotomy and an anesthetist stand-by.

Dilemmas and Discussion

The fetus presenting by the breech at term, as compared to the cephalic presentation, is at greater risk of perinatal and neonatal morbidity and mortality, due principally to birth trauma birth asphyxia and congenital anomalies. There are two schools of thought regarding the management of a non-anomalous, term breech fetus.

Elective Cesarean

Proponents of this policy “elect” for an elective cesarean because of the concern for birth asphyxia and possibility of unexpected arrest of fetal parts at vaginal delivery. Most couples today, in this increasingly competitive world, opt for a small family but a “quality” family and hence any risk of compromised perinatal and neonatal outcome is not accepted. Also, ethical and medicolegal issues prevent many obstetricians from contemplating a vaginal trial for the term breech. Thus, the pendulum for the management of the term breech fetus has swung from routine vaginal breech delivery for all cases to the present trend of elective cesarean section for all.

The timing of the cesarean for breech seems important in decreasing neonatal morbidity. Cesarean before labor was better than a cesarean in early labor, which in turn was better than a cesarean in late labor. In this study by Su et al., of those patients who labored with a term breech, the risk of poor outcome was increased with labor augmentation, a longer second stage of labor and birth weight less than 2.8 kg.

Selective Cesarean or Trial of Breech

Obstetricians skilled in vaginal breech delivery argue that the above intrapartum risks with vaginal delivery are overstated due to improperly carried out research studies which involve selection bias, failure to comment on intrapartum management and no assurance that the accoucheur is skilled in the art of vaginal breech delivery. These proponents also point that the persistent breech is a result of poor fetal quality with respect to neuromuscular dysfunction and hence the mode of delivery is unlikely to change the perinatal outcome to that of vertex. Also, cesarean alone cannot guarantee a good neonatal outcome as maneuvers of delivering a breech fetus by cesarean are similar to that of a vaginal breech delivery.

All said and done, as more and more number of women undergo cesarean for breech, obstetrical trainee doctors have less opportunities to acquire the skills of conducting a vaginal breech delivery. A time would come when this art would be permanently lost. This would result in a greater neonatal adverse outcome in the event of an imminent breech delivery without adequate facilities of an experienced accoucheur. In the bargain, the prevailing enthusiasm for offspring of the highest quality in a one- or two-child family will continue to result in the frequent use of cesarean for the breech fetus.

Breech with Previous Cesarean Section: A Management Dilemma

Ophir et al. conducted a study of 71 breech births after previous cesarean and concluded that a trial of breech seems reasonable in carefully selected cases. Neonatal morbidity did not differ for women who delivered vaginally or by cesarean though maternal febrile morbidity was significantly higher in the cesarean group.

Preterm Breech

Cesarean was associated with a significant decrease in intraventricular hemorrhage and neonatal deaths in infants weighing less than 1.25 kg. Several studies suggest that nonfrank breech presentations are at greater risk for cord accidents and that fetuses of earlier gestations may be most likely to benefit from a cesarean because of the potential to avoid mechanical complications like head entrapment. Fetal mortality and morbidity associated with vaginal delivery of a term breech is three times that of cephalic presentations. The worst prognosis is in the preterm breech. In difficult vaginal breech delivery, the risk of fetal damage is 20%, in easy births it is 3.5%. Fifteen percent of fetal deaths occur during labor and intracranial hemorrhage associated with a preterm vaginal breech delivery is a major cause of fetal mortality.

Changing Trends in Cesarean Section

HISTORY OF CESAREAN SECTION

Cesarean section is one of the oldest operations in surgery and probably derived its name after the births of Julius Caesar. The monograph of Trolle traces the history of cesarean section (CS) which was first performed on a dead patient. The case often cited as representing the first CS performed on a living woman is attributed to a German named Jacob Nufer, who performed the operation on his wife in 1500 AD. His wife survived and lived to give birth to two subsequent children by the vaginal route. The case was reported almost a hundred years later. CS on the living was first recommended by Francois Rousset in 1581 although he had never performed or witnessed the operation and his information was based on letter from friends. Authoritative statements by dependable obstetricians about early use of the operation, however, did not appear in literature until the middle of 17th century when it was employed in rare and desperate cases and was usually fatal. The appalling maternal mortality rate of CSs continued until the beginning of the 20th century and the rate reported in 1865 was 85%. A modification in technique was introduced by Porro of Italy in 1876 which consisted of amputation of the body of uterus and fixing the cervical stump to the lower angle of the abdominal wound. This reduced the maternal mortality to half. The turning point came in 1882 when Max Sanger introduced suturing of the uterine wall. The introduction of uterine sutures reduced the mortality rate of the operation from hemorrhage. However, generalized peritonitis remained the dominant cause of death and various operations were devised to combat this problem. The first extraperitoneal operation was described by Frank in 1907 and later modified by Latzko (1909) and Waters (1940). In 1912, Krong postulated that the main advantage of the extraperitoneal technique consisted of opening the uterus through its thin lower segment and then covering the incision with the peritoneum. The lower segment technique was introduced by Beck in 1919 and later popularized by Delee (1922). In these, however, the uterine cavity was opened by a vertical incision rather than a transverse one. An important modification recommended by Kerr in 1926 was to open the cavity by transverse rather than a longitudinal uterine incision.

INCIDENCE

The CS continues to be one of the most important surgical interventions performed in obstetrics practice. Its rate has increased dramatically over the past three decades. Taffel et al. reported the rate as 9.5% in 1965, 15% in 1978 and as high as 25% in 1988. The cesarean delivery rate decreased from 1987 to 1996, but has been on the increase since 1996. There is no single factor that can account for the dramatic increase in cesarean deliveries during the last 30 years. The distribution of maternal age and parity has changed over the course of the past four decades, with many women choosing to delay childbirth and limiting their number of pregnancies. CS rates have been shown to be related to the socioeconomic status of the patients, the proportion of patients purchasing private obstetric care, the risk of litigation, the increased availability of medical technology such as fetal monitoring and neonatal facilities, and patient demand for CS. The widespread use of repeat elective CS for women who have had a previous CS and maternity unit policies to deliver breech presentations and multiple pregnancies by CS have also made a significant contribution to its increasing rate. Teaching hospitals tend to have lower cesarean delivery rates than private institutions. This is mainly due to the role of residents and the use of clinical guidelines.
In the seventies dystocia accounted for 30% increase in CS rate. However, the vast majority of cesarean deliveries performed because of dystocia were often in pregnancies with normal sized infants, therefore, the increase in rate was difficult to understand. O’Driscoll and Foley in 1983 advocated the use of oxytocin and partogram and reduced the number of CSs due to dystocia. In 1993, Bhide in his study showed a decline in the rate of CSs due to dystocia, over the last five years. He attributed it to the active management of labor. A similar trend has been reported by other workers also.

Breech presentation at term is encountered in 3–4% of all pregnancies. Breech presentation is the primary indication for 10% of all CSs; overall 60–88% of pregnancies with breech presentation are delivered by CS. Williams reported breech presentation as the indication in 15% of all lower segment cesarean section. However, CS rates vary with gestational age, at term 91% women with a breech presentation had a CS, while at less than 28 weeks, the CS rate was less than 40% (evidence level 3). In the CEDS1 project 27/28 report, survival rates were significantly greater in those infants delivered by CS (86.5%) than those delivered vaginally (77.4%) (evidence level 3). In a retrospective study, conducted at UCMS and GTB Hospital, Delhi, the incidence of CS for breech was 40%. Apart from the parity, gestational age and the weight of the baby, other factors that determined the rate, in this study, included the socioeconomic status of the women and their reluctance for an operative delivery.

One-third of all sections performed each year in the United States are for women with previous cesarean delivery. Nine percent of women giving birth in England and Wales have had a previous CS. Repeat CS contributes about 14% to the overall CS rate. An increase in the percentage of women who have had a previous CS in a population will result in a disproportionate increase in the overall CS rate. Before 1978, trial of labor was virtually unknown. But now review of literature has documented the safety, acceptability and high rate of subsequent vaginal delivery in cases of previous CS. Overall, the chances of successful planned vaginal birth after cesarean (VBAC) are 72–76%. The single best predictor for successful VBAC is a previous vaginal birth, particularly previous VBAC which is associated with an approximately 87–90% planned VBAC success. The risk of uterine rupture in such cases is 22–74 per 10,000. Patients with induced labor, no previous vaginal birth, body mass index greater than 30, and previous CS for dystocia have more chances for unsuccessful VBAC (Table 1).

Although according to Royal College of Obstetricians and Gynaecologists (RCOG) recommendations, women with a prior history of two uncomplicated low transverse CSs, in an otherwise uncomplicated pregnancy at term, with no contraindications for vaginal birth may be considered for planned VBAC (Grade B recommendation). Analysis of the NICHD study showed that there was no significant difference in the rates of uterine rupture in VBAC with two or more cesarean births (9/975, 92/10,000) compared with a single previous cesarean birth (115/16,915 and 68/10,000).

- **Induction and augmentation:** Patients with previous cesarean delivery have a two- to three-fold increased risk of uterine rupture and about 15-fold increased risk of CS in induced and/or augmented labor compared with spontaneous labor. Induction/augmentation in such patients should be preceded by careful obstetric assessment and maternal counseling, strict oxytocin dose titration and careful serial cervical assessments (Evidence level 3). Studies have shown a small but statistically significant higher uterine rupture risk (87/10,000 versus 29/10,000) with prostaglandin induction compared with nonprostaglandin induction.

- **Uterine exploration:** Though uterine exploration is not recommended after vaginal delivery but is still done by many. If a rent is found not communicating with the peritoneal cavity, there is no bleeding and the patient is stable, laparotomy is not required but trial of scar in a subsequent pregnancy is not recommended.

Fetal distress has accounted for 10–15% increase in the CS rate. Dalvi from Bombay reported that fetal distress was the indication in 26.5% of all CSs. Overall an abnormal cardiotocogram was noted in 69% of singleton pregnancies delivered by CS for presumed fetal distress. Systematic review
of 9 randomized controlled trial over 20 years (n = 18,561 women) have shown that the use of electronic fetal monitoring (EFM) during intrapartum care results in increased CS rates (RR, 1.4; 95% CI, 1.23–1.61). This increase is less marked if fetal blood sampling (FBS) is used (RR, 1.27; 95% CI, 1.08–1.51 for EFM with FBS, compared with RR, 1.41; 95% CI, 1.23–1.61 for EFM without FBS). It is now recommended that when CS is contemplated because of abnormal fetal heart pattern, in cases of suspected fetal acidosis, FBS should be offered if technically possible and there are no contraindications (Grade B recommendation). The distressed fetus often responds favorably to change in maternal position and use of oxygen, so that in a few cases cesarean delivery can be avoided. In cases complicated with thick meconium, Wennstroms and Parsons reported a significant reduction in the CS rate with the use of intrapartum saline infusion. In a study carried out at the author’s hospital, amnioinfusion was carried out in cases with thick meconium using 18 G suction catheter as a part of postgraduate thesis. It was found to be a safe and simple technique that resulted in decreased CS rate.

Maternal request for CS is an indication which is steadily increasing in today’s world. The rates of preference for CS expressed by the women surveyed during pregnancy in UK, Australia and Sweden range from 6% to 8%. Within these studies there was a consistent relationship between women’s preference for CS and either previous CS, negative birth experience, a complication in the current pregnancy or a fear of giving birth. RCOG recommends that maternal request is not on its own an indication for CS and specific reason for the request should be explored and discussed. If she requests a CS because she has a fear of childbirth, she should be offered counseling (such as cognitive behavioral therapy) to help her address her fears in a supportive manner (Grade A recommendation).

**CHANGING TRENDS IN OPERATIVE TECHNIQUE OF CESAREAN SECTION**

The endpoint of successful CS is a healthy mother and healthy child. In the recent years maternal risk from CS has declined significantly and major factors responsible for the reduced risk include improvement in surgical and anesthetic techniques, safe blood transfusion and the use of antibiotics. Durphy et al. in 1991 showed that the relative risk of neonatal asphyxia can be reduced to half if the decision to delivery interval is kept less than 20 minutes. The other factors that need in-depth discussion are the following:

**Abdominal Incision**

The skin incision is chosen to optimize access to the surgical field thereby minimizing maternal morbidity while producing a maximal cosmetic effect. Previously vertical incision was in vogue due to superior access to surgical field and potential for extending the incision. Nowadays, transverse incision is recommended as it is associated with better cosmetic effect, decreased postoperative pain and decreased inhibition of deep respiration (Grade B recommendation). The transverse incision of choice should be the Joel Cohen incision (straight skin incision 3 cm above symphysis pubis, subsequent tissue layers are opened bluntly) because it is associated with shorter operating time and reduced postoperative febrile morbidity (Grade A recommendation).

**Bladder Flap Formation**

This is dissection of bladder from lower segment. Hohlgenschwandtner et al. compared 102 women undergoing CS with “bladder flap” formation or “no bladder flap” formation. They found decreased operative time, blood loss and need for postoperative oral analgesics without an increase in infectious morbidity in the “no bladder flap formation” group. Eisenkop et al. in a retrospective study found rate of bladder injury to be 0.3%. These injuries most commonly occurred during formation of bladder flap, whereas only 2 out of 23 cases occurred during extension of uterine incision.

**Extension of Transverse Uterine Incision**

Extending the uterine incision either by blunt dissection or by scissors was studied by Rodriguez et al. They found no difference in operative time, blood loss, infectious complication or risk of extension between the two. When there is a well formed lower uterine segment, blunt rather than sharp extension of the uterine incision should be used as it reduces blood loss, incidence of PPH (Grade A recommendation). Under unusual circumstances variation in the uterine incision may be required.

- **Classical CS:** This is done in cases where the lower segment is not easily accessible; there is extreme kyphoscoliosis, dense bladder adhesions, myoma in the lower segment, carcinoma cervix, narrow lower segment and in some cases of renal transplantation where the kidney is close to or obscuring the lower segment.
- **Vertical lower segment:** In obstructed labor with the head deeply engaged and the lower segment thinned out, manipulations to dislodge the head may sometimes result in lateral extension and involvement of uterine arteries. In this circumstance, a low vertical incision is recommended. As the lower segment is wide here, extension to the upper segment is unlikely. However, in preterm delivery when the lower segment is not formed, extension to the upper segment may occur.
- **J-shaped incision:** This type of incision is preferred over the classical T-shaped in cases of transverse lie, hand prolapse and large baby to avoid extension. Table 2 shows the risk of uterine rupture in relation to scar location.
Delivery of Fetal Head

Use of ventouse or forceps, as compared to manual extraction of head provided no benefit in terms of uterine incision extension or blood loss. Forceps should only be used at CS if there is difficulty in delivering the baby’s head. The effect on neonatal morbidity of routine use of forceps is uncertain (Grade C recommendation).

Removal of Placenta

The Cochrane database meta-analysis of the topic demonstrated that there is a clinically and statistically significant decrease in maternal blood loss and postpartum endometritis associated with the traction method of placental removal as compared with manual removal. Sponge curettage of uterine cavity did not decrease the risk for endometritis.

Exteriorization of Uterus for Repair of Hysterotomy

The Cochrane database in a meta-analysis found no difference in blood loss or infectious complications between exteriorization and in situ repair of hysterotomy incisions. Exteriorization may facilitate repair but there is insufficient evidence to support its routine use. So, exteriorization of the uterus is not recommended because it is associated with more pain and does not improve operative outcome such as hemorrhage and infection (Grade A recommendation).

Closure of Uterine Incision

Both one layer and two layered closure of uterine incision have been practiced currently. One layered closure has shown to decrease operative time and blood loss in the short term. In long term, the risk of uterine rupture during subsequent labor is increased. Bujold et al. in an observational cohort study found a four-fold increased risk of uterine rupture among patients with previous one layered closure of uterine incision. The current recommendation is to close the uterus in two layers as the effectiveness and safety of single layer is uncertain (Grade B recommendation).

Closure of Visceral Peritoneum (Bladder Flap) and Parietal Peritoneum

Except for restoring the anatomy to preoperative state there is less data to support closure of peritoneum. In a study the peritoneal closure group was found to have increased incidence of cystitis, antibiotic use and analgesia, purportedly because of subperitoneal pocket formation which served as a nidus for infection.

The Cochrane database, in its meta-analysis concluded that nonclosure of parietal peritoneum reduces operative time without increasing infectious complications and may offer decreased analgesic requirement. The current recommendations are that neither the visceral nor parietal peritoneum should be sutured at CS as this reduces operative time and the need for postoperative analgesia (Grade A recommendation).

Closure of Subcutaneous Tissue

Routine closure of the subcutaneous tissue space should not be used, unless there is more than 2 cm subcutaneous fat, because it does not reduce the incidence of wound infection (Grade A recommendation).

Antibiotic Prophylaxis

A multitude of studies have consistently shown that parenteral antibiotic prophylaxis at the time of cesarean results in significant reduction in infectious complications. So, women having a CS should be offered prophylactic antibiotics, such as single dose of first generation cephalosporin or ampicillin to reduce risk of postoperative infections, which occurs in about 8% of women (Group A recommendation).

Modified Technique for Lower Segment Cesarean Section

Misgav Ladach Method

The Misgav Ladach method was based on the principle to minimize tissue trauma by reducing unnecessary dissection. The important steps of procedure are as follows:

- Joel-Cohen skin incision is given
- Uterovesical pouch is opened and the bladder is pushed down with blunt dissection
- Small transverse incision in the lower uterine segment is made to accommodate two fingers and the incision stretched manually
- Uterus is exteriorized after delivery of the fetus and placenta
- Single layer uterine closure; parietal and visceral peritoneum are left unsutured
- Abdominal closure is done in two layers (rectus sheath and skin)
A number of prospective studies have shown that CS performed by the Misgav Ladach technique compared to the conventional Pfannstiel method have a shorter operative time and less wound infection, postoperative pain and febrile morbidity.

**CONCLUSION**

Cesarean section is more traumatic than an easy vaginal delivery and an elective CS is preferred over a difficult vaginal delivery to avoid fetal and maternal trauma. Complaints and litigations are more frequent in obstetrics and gynecology than in other divisions or care groups of most hospitals. This is inevitable since the nature of work in reproduction generates high expectations from the family where everyone hopes for the best outcome for the mother and her baby.

**BIBLIOGRAPHY**

INTRODUCTION

Postpartum hemorrhage (PPH) is the single most important cause of maternal death in the developing countries which accounts for 130,000 deaths per year in India. About 88% occur within 4 hours of delivery and 70% are due to atonic PPH. This PPH can be prevented by active management of third stage of labor, identification of risk factors, and being on alert, should active management fail.

In 2003, the International Confederation of Midwives (ICM) and International Federation of Gynecologists and Obstetrics (FIGO) published a joint statement on the prevention of PPH. In addition to recommending that birth attendants have the knowledge, skills and judgment to carry out active management of third stage of labor and access to needed supplies and equipment. The statement also recommends that active management should be offered to all women in labor.

The ICM/FIGO definition of active management of third stage of labor includes:
- Delivery of oxytocin [10 international units (IU) intra-muscular (IM)] within 1 minute of birth of the baby
- Clamping of the cord once it stops pulsating
- Controlled cord traction
- Massage of the fundus of the uterus until it is contracted.

ACTIVE MANAGEMENT

A systematic review comparing active versus expectant (physiological) management of third stage identified five relevant randomized controlled trials, four of which the reviewers assessed to be of good quality. In these trials expectant management was defined as awaiting spontaneous delivery of the placenta with the aid of gravity or nipple stimulation. Cochrane reviewers advocate for active management of third stage as the routine management of choice for women planning a vaginal delivery in hospital, and suggest that additional research is needed to clarify the implications in other settings including home births. Active management is, however, associated with an increased risk of unpleasant side effects (e.g. nausea, vomiting) and hypertension where ergometrine is used (Cochrane review, 2006) (Table 1).

*95% confidence interval  
†Number needed to treat  
Abbreviation: PPH, Postpartum hemorrhage
The findings show a conclusive benefit for active management, with an approximately 60% reduction in the occurrence of PPH more than or equal to 500 mL and 1,000 mL, hemoglobin value of less than 9 g/dL at 24–48 hours after delivery and the need for blood transfusion. The need for therapeutic uterotonic agents was also reduced by 80%. These results were all highly significant, as indicated by the 95% (confidence interval) CI. A higher incidence of increased blood pressure (BP) following delivery (diastolic BP > 100 mm Hg), nausea and vomiting were observed. These appear to be a function of the chosen uterotonic, especially with ergot preparations and not with oxytocin.

There is a gap in the current research regarding what impact each of the individual components of active management has on preventing blood loss. It appears that the key element of active management is the administration of oxytocic drug.

**OXYTOCIC DRUGS FOR ACTIVE MANAGEMENT OF THIRD STAGE OF LABOR**

Commonly used drugs are:
- Oxytocin
- Ergot alkaloids (ergometrine/methyl ergometrine)
- Misoprostol
- Carbetocin (15-methyl PGF, alpha).

One debated aspect of active management is the ideal choice of prophylactic uterotonic. While some argue that currently there is little evidence that any route, dose or timing of oxytocin administration is superior, there has in fact, been a fair amount of research done which compares the effects of oxytocin, ergonovine or a combination of these drugs, administered intravenously (IV) or intramuscularly (IM).

**Oxytocin versus no Uterotonic**

In a study covering over 3,000 women there were clear benefits to women who received prophylactic oxytocin as a part of the third stage of labor when compared to women who did not receive any uterotonics. The benefits relate specifically to indicators of blood loss such as PPH, whether more than 500 mL or more than 1,000 mL and the need for therapeutic oxytocics. In this study, no differences were seen in the need for blood transfusion or manual removal of placenta. The results of these reviewers suggest that oxytocin appears to be the agent of choice of active management of third stage of labor (AMTSL) in low risk women. Prophylactic oxytocin may be given as 10 IU IM, 20–50 IU/L, IV drip run at 100–150 mL/min. or 5 IU IV push. Some authorities caution against the use of bolus of IV oxytocin, citing small studies which suggest that such practices could compromise women’s hemodynamic state. When caring for women who give birth without pain medication, care providers should remember that IM oxytocin is relatively painful.

**Oxytocin versus Ergot Alkaloids**

*Cochrane Review*

The drugs used in AMTSL are oxytocin and ergometrine, given alone or in combination. They may be given IM or IV and the injection may be administered with the crowning of the head, after delivery of the anterior shoulder, after delivery of the infant or after delivery of the placenta.

Oxytocin provides rhythmic contractions of the uterus augmenting retraction and its effect is noticeable in about 3 minutes after an IM injection.

Ergometrine by IM injection results in a more prolonged contraction with retraction and its effect is noticeable in about 7 minutes. When either drug is given IV, the uterine contraction commences in 30–40 seconds.

In a study covering over 2,800 women, overall there is little evidence of differential effects of these two oxytocics. The oxytocin is associated with fewer manual removals of the placenta, less raised BP than with ergot alkaloids. For all other outcomes definite conclusions can not be drawn.

**Oxytocin versus Oxytocin: Ergometrine**

*Cochrane Review*

A systematic review comparing oxytocin (syntocinon) versus oxytocin–ergometrine (syntometrine) for AMTSL, identified six relevant trials (involving 9,332 women). The combination was associated with a small but statistically significant reduction in the risk of blood loss more than 500 mL. However, there was no difference between groups for blood loss of more than 1,000 mL. The oxytocin–ergometrine was associated with statistically significant increase in the risks of nausea, vomiting and elevated diastolic BP. The advantage of a reduction in the risk of PPH, between 500 mL and 1,000 mL blood loss, needs to be weighed against the adverse side effects associated with the use of oxytocin–ergometrine combination.

The likely explanation for these differences is that ergot preparations act systemically on smooth muscles, whereas oxytocin is specific for uterine smooth muscle. Oxytocin causes increased contraction strength and frequency, but the uterus does not undergo tetanic contraction, as is the case with an ergot. Studies undertaken by the WHO also favor oxytocin because it is more stable when exposed to heat and light compared to ergot preparations. This makes oxytocin more useful in settings where storage capabilities, especially refrigeration, may be an issue. Trials have been performed using a synthetic oxytocin analog, carbetocin, which has a prolonged action (Dansereau, 1999). Results are favorable, but the drug is not easily available in the United States.
Misoprostol

Recent research focusing on AMTSL has examined alternatives to oxytocin and syntometrine. The majority of randomized controlled trials on the topic published in the last 8 years have investigated use of misoprostol, a prostaglandin E1 analog. Misoprostol is inexpensive, stable, easily stored and therefore, has potential to be particularly useful in developing countries. Three systematic reviews have been completed on misoprostol use since, 2002. This work concludes that misoprostol results in higher blood loss than conventional prophylactic uterotonics and is associated with significant increase in rates of shivering and fever (Gulmezoglu, 2001, 2004). Clearly, the presence of prostaglandin induced pyrexia and shivering in the postpartum period may lead to confusion in the diagnosis of sepsis.

Injectable Prostaglandins

Injectable prostaglandins are another alternative to conventional uterotonics. Mean blood loss appear to be reduced. Prostaglandin related side effects, especially shivering, pyrexia, nausea, vomiting and diarrhea were frequent and consistent across trials. The injectable prostaglandins appear to be more appropriate for the use in the treatment of PPH than its prevention.

Carboprost (15-methyl PGF2 Alpha)

The use of carboprost in the AMTSL, the clinical evidences suggest that carboprost in low dose IM (125 µg) is for AMTSL and the high dose IM (250 µg) is for high risk cases and management of PPH. This drug is mainly compared with methyl ergometrine.
Postpartum Conditions
INTRODUCTION

Postpartum hemorrhage (PPH) is a life-threatening emergency with possible grave maternal outcome. According to the World Health Organization (WHO) 5,29,000 women die annually due to complications of pregnancy and child birth, and 99% of deaths occur in developing countries. Incidence of PPH varies widely because of lack of uniformity in definition and deficient data collection. Estimated incidence is 4–6% of all deliveries and the recurrence risk is 20–25%. Postpartum hemorrhage contributes to about 25% of all maternal deaths in India. It is also an important cause of postpartum morbidity like chronic anemia, fatigue, failure of lactation, infections and associated risks of blood transfusions, postpartum depression and pituitary necrosis (Sheehan’s syndrome). All these factors would adversely affect the care of newborn and impose a financial and psychological burden on the entire family unit. Various causes of hemorrhage resulting in significant maternal mortality and morbidity have been illustrated in Figure 1. Predisposing factors and causes of immediate postpartum hemorrhage are presented in Table 1.

DEFINITION

Primary postpartum hemorrhage is defined by the WHO as blood loss from genital tract more than 500 mL in the first 24 hours of delivery. The American Congress of Obstetricians and Gynecologists (ACOG) has defined PPH as a decrease in hematocrit by 10% or a need for blood transfusion in 24 hours after delivery. Blood losses up to 500 mL are generally well tolerated by healthy women because of the volume expansion and relative hemodilution in pregnancy. Recent reports have stated that approximate blood loss at normal delivery is 500 mL, at lower segment cesarean section (LSCS) is 1,000 mL and at postpartum hysterectomy is 1,500 mL and not all women are compromised even in these situations. On the other hand, Indian women are small built with low blood volumes, prevalence of anemia during pregnancy is as high as 80% and it is not possible to perform regular hematocrit counts in busy hospitals with limited resources. Thus, clinical judgment along with amount of blood loss should define PPH.

Fig. 1: Incidences of some causes of obstetrical hemorrhage and their contribution to maternal death from hemorrhage. Percentages are approximations because of different classification schemata used. Source: Al-Zirqi (2008)\textsuperscript{a}, Zwart (2008)\textsuperscript{b}, Chichkali (1999)\textsuperscript{c}
ETIOPATHOLOGY

There are four primary causes of PPH, the four-Ts namely: Tone (atonic uterus), Tissue (retained placenta), Trauma and Thrombin (coagulation defects). The underlying risk factors for each is depicted in Table 2.

CLINICAL PRESENTATION (TABLE 3)

Clinical features depend on the antenatal hemoglobin levels and the amount of bleeding leading to hypovolemia and acute anemia.

It is important to note that in a malnourished or anemic patient the signs of shock can appear with mild bleeding (< 500 mL).

DIAGNOSIS

In majority of cases profuse bleeding at the time of cesarean or after vaginal delivery makes the diagnosis of PPH obvious. However, visual estimation of the amount of blood loss is always grossly inaccurate. Following methods have been proposed for estimation of blood loss at delivery but their usefulness is not yet substantiated:

- Collection of blood into bedpan or plastic bags as used in a study by WHO
- A plastic calibrated drape and receptacle has been used successfully to collect blood in a study in Karnataka

Abbreviations: PPH, postpartum hemorrhage; H/O, history of; LSCS, lower segment cesarean section; ITP, idiopathic thrombocytopenic purpura
Weighing the sponges soaked in blood during cesarean and calculating the change in weight of the dry and soaked sponges.

**Acid/alkali hematin method**: The collected blood is converted to hematin and measurements of actual blood loss are calculated by colorimeter readings.

Monitoring of vitals and fundal height of uterus in each patient after delivery for early detection of abnormal bleeding or signs of hypovolemia is the best method to diagnose PPH because sometimes the blood loss is not severe but there is a constant trickle which may over a period of time assume significant proportions. Besides, bleeding may not be obvious in rare cases of broad ligament and retroperitoneal hematomas and uterine rupture. Diagnosis of the underlying cause of bleeding depends on the presence of antecedent risk factors as given in Table 2 and a careful examination of the patient. Ultrasound may be helpful in a few cases of uterine scar rupture, retained placenta, morbid adherent placenta and supraselevator hematomas. Calculation of maternal total blood volume is shown in Table 4.

**MANAGEMENT**

Principle of management is to ascertain the cause of bleeding and initiate prompt measures to control it. Interval between delivery, diagnosis of PPH and the start of resuscitation with appropriate medical or surgical measures is an important prognostic factor for subsequent maternal morbidity and mortality associated with PPH.

**Resuscitation**

- It is important to work as a team, call for help, summon senior obstetrician and anesthetist and enough junior staff. Alert blood bank and operation theater of the emergency.
- Perform a quick but thorough physical examination.
- Raise the foot end of patient.
- Administer oxygen by mask.
- Secure intravenous access with at least two large bore IV cannula.
- Collect adequate sample, about 20 mL, for blood grouping, cross matching and complete blood counts, if necessary for coagulation profile.
- Arrange for at least 4–6 units of blood in severe bleeding and also for fresh frozen plasma and cryoprecipitate if coagulopathy is suspected.
- Start fluid replacement with rapid infusion of crystalloids like normal saline 0.9% or Ringer’s lactated solution to restore blood pressure. 5% dextrose solution is hypotonic and is not helpful for acute volume expansion. Colloids like albumin or Hartman’s solutions may be used if only there is delay in obtaining blood. Blood or blood component therapy should be initiated as soon as available.
- Self-retaining catheter is to be inserted as full bladder interferes with contraction of uterus.
- Monitor vitals, urine output, bleeding p/v and fundal height. In severe bleeding, monitoring by electrocardiography (ECG), central venous pressure (CVP) line, pulse oxymetry is necessary.
- Nonpneumatic antishock garment has been shown to reduce blood loss by 50% and may be useful as a first aid measure in low-resource settings to obtain time to shift the patient to tertiary hospital. However, larger studies are required to demonstrate benefit on maternal mortality.
**Management According to Cause of Bleeding**

**Uterine Atony**

Presence of a soft and boggy uterus on per abdomen palpation suggests uterine atony. If the placenta is still attached post delivery, active management with oxytocin and controlled cord traction is attempted. Manual removal of placenta is done if required under general anesthesia. Bimanual compression of the uterus and massage with abdominal hand is carried out along side.

**Pharmacological Methods (Table 5)—Drugs Used to Aid Contraction of Uterus**

**Oxytocin:** It acts rapidly, latency period is less than 1 minute after intravenous injection. Higher concentration of oxytocin should be avoided as it does not improve the efficacy but can lead to side effects like water intoxication.

**Ergot alkaloids:** Methylergometrine, methyl ergonovine and syntometrine (5 IU oxytocin + 500 mg ergometrine maleate) have a prompt and sustained action. The latter two are not available in India.

**Prostaglandins:** Prostaglandins have potent uterotonic effects.

- **15-methyl prostaglandin F\textsubscript{2α}:** About 75% of the patients will respond to the first dose and the overall response is 95%. It is less effective in presence of chorioamnionitis.

- **Misoprostol:** It is rapidly absorbed following oral administration, plasma concentration increases rapidly to peak in 30 minutes while with vaginal administration the peak is reached in 1.5 hours. Its advantages are that it is a strong uterotonic, can be given orally, is inexpensive and does not need refrigeration for storage unlike oxytocin.

  Studies have found that neither intramuscular prostaglandins nor misoprostol (oral or rectal) given prophylactically was preferable to conventional oxytocin for third stage labor management, although prostaglandins are useful in treatment of intractable postpartum hemorrhage.

**Recombinant factor VIIa:** It has been used successfully in selected patients with coagulopathies and intractable hemorrhage. It is very expensive and more studies are required to assess its actual efficacy in PPH.

**Calcium gluconate:** It is not a uterotonic but may be useful in uterine atony secondary to use of antenatal magnesium sulfate or nifedipine.

**Nonpharmacological Methods**

These are intended to control hemorrhage until uterus itself can secure hemostasis by contraction, retraction and coagulation. They are reasonable alternatives to surgery in uncontrolled bleeding and may be helpful to avoid hysterectomy in patients keen to preserve fertility especially in cases of hemorrhage due to placenta previa and adherent placenta. Also, they can help to obtain time for transfer of the patient to a tertiary center.

**Uterine tamponade:** This method increases intrauterine pressure and stems the bleeding. It carries a potential risk of infection and trauma. Besides, it may conceal actual bleeding and give a false sense of security. Close monitoring with broad spectrum antibiotics and oxytocics should be given along side. The various methods are:

• **Uterine packing**: Uterus is packed from the fundus with ribbon gauze soaked in povidone-iodine including the vagina. Self-retaining catheter is also inserted.

• **Balloon tamponade**: Tamponade of uterine cavity using a Sengstaken-Blakemore tube has been reported. The tube is left inflated for 24 hours and then deflated. Several studies have reported the use of large 30 mL Foley catheter placed into the uterine cavity. These are cheap, simple and effective methods in relevant situations.

• **Uterine artery embolization**: It is a safe alternative in centers with the radiological interventional facilities. Up to 95% success rates have been recorded with this method. This method is successful only if circulation in vessels is not compromised. Embolization gives better results in retroperitoneal hematomas as surgery is difficult due to distorted anatomy. The occlusion is carried out by injecting particles of gel foam or polyvinyl alcohol through the internal iliac artery. Side effects reported are hematoma at catheterization site, technical difficulty in accessing the uterine arteries and infection. Disadvantages are high cost of set-up and need of trained radiologists. Besides, further studies are required to prove its efficacy in PPH.

**Surgical Management**

Surgery involves laparotomy followed by either a conservative approach or the radical procedure of hysterectomy based on the general condition of patient, the facilities at the hospital, skill of the operating surgeon and the desire of the patient.

Conservative surgical methods are useful when conventional methods have failed and the patient is desirous of conserving fertility. They can be performed if the patient is hemodynamically stable. However, the surgeon needs to be skilled to perform the procedures.

**Uterine Artery Ligation**

The procedure is useful as 90% of blood supply to the gravid uterus comes from uterine artery. It is reported to be a satisfactory technique to control postcesarean hemorrhage and is easy to perform with minimal complications. It however may not be successful to control bleeding in cases of placenta previa or uterine rupture.

**Ovarian Artery Ligation**

It is usually performed with uterine artery ligation for better control of bleeding in some cases. Most patients are reported to resume normal menstruation and fertility despite an 80% decrease in the arterial pulse pressure with concomitant ligation of uterine and ovarian arteries.

**Internal Iliac Artery Ligation**

Bilateral artery ligation reduces pulse pressure by 85% but is seen to benefit only 48% cases. It requires great degree of surgical expertise and is reported to increase the total blood loss, operating time and operative morbidity. Hence, it is reserved for stable patients keen to preserve uterus for future childbearing.

AbdRabbo has reported 100% success with the judicious stepwise ligation of uterine vessels to control PPH.

**Hemostatic Compression Sutures**

These sutures when applied to the uterus have been reported to stop hemorrhage even in cases of placenta previa/accreta and disseminated intravascular coagulation (DIC). B-Lynch suture consists of application of a brace suture that compresses the fundus and lower segment of uterus. This method is simple, effective and safe. To test the potential efficacy of the suture it is recommended to check if bleeding stops by applying bimanual compression to uterus. Follow-up studies though limited have not shown any significant morbidity associated with the method. Hayman’s uterine compression suture and Cho multiple square suture are modifications of B-Lynch procedure with limited published data on their efficacy and safety.

**Hysterectomy** is the final life-saving measure in some cases of uncontrolled PPH.

**Genital Tract Trauma**

A well contracted uterus in the presence of hemorrhage warrants a thorough inspection of the genital tract. Adequate light and exposure with good assistance are necessary. It is best to start exploration from the highest point of genital tract and proceed downward as excess bleeding can obstruct the view of lower parts. Cervix should be explored with four ring forceps to inspect all quadrants. In large lacerations, suturing requires good anesthesia and an experienced surgeon. Laparotomy should be considered in extensive lacerations involving vaginal vault and in high cervical tears to help in the timely detection and management of broad ligament hematomas.

**Morbid Adhesions of Placenta**

It should be suspected in cases of PPH with retained placenta where no plane of cleavage is found between decidua and placenta and manual removal of placenta fails even under anesthesia. It may be detected antepartum by ultrasound in patients with previous cesarean and anterior placenta previa. The usual treatment is hysterectomy. In selected cases, conservative treatment to preserve fertility like uterine vessel ligation or embolization may help. A few case reports of leaving adherent placenta in situ with close follow-up of bleeding and sepsis with serial ultrasounds have shown success but the efficacy is yet to be proved.

**Coagulopathies**

Vigilant delivery in high-risk cases and prompt resuscitation with adequate fluids, blood constituents and coagulation...
factors is the most important factor in preventing maternal mortality in such cases. The underlying cause like sepsis, pre-eclamptic toxemia (PET), etc. need to be dealt vigorously.

**Uterine Inversion**

Inversion is suspected if the fundus of uterus cannot be felt per abdomen after delivery. The patient may suddenly develop acute pain in abdomen with neurogenic shock. Acute inversion can be managed by manual reposition (Johnson’s method) or hydrostatic replacement with warm saline (O’Sullivan method). Tocolysis or general anesthesia may be required to facilitate reposition. Use of uterotonic is stopped till the correction is performed after which bimanual massage and vigorous use of uterotonic will be required to contract the uterus. Laparotomy with surgical reposition or hysterectomy may be required in some cases.

**Secondary Postpartum Hemorrhage**

Excessive blood loss after 24 hours of delivery in postpartum period is termed secondary or “late” PPH. Retained placental tissue is the most common cause followed by infection causing subinvolution of placental site and sloughing of lacerations. Rare causes are chronic uterine inversion, placental polyp, choriocarcinoma. Replacing lost blood, use of broad-spectrum antibiotics, surgical evacuation of uterus if possible under ultrasound guidance are usually done. Occasionally, laparotomy and hysterectomy may be required. It is important to obtain histopathological diagnosis of tissue obtained to rule out choriocarcinoma.

**Preventive Management**

Active management of third stage of labor—this should be encouraged in all cases if possible. It includes administration of prophylactic uterotonic at birth of baby, early cord clamping and placental delivery with controlled cord traction. Uterotonic has a definitive role in preventing PPH, while the latter two have not been shown to prevent PPH. Oxytocin or ergometrine are the drugs of choice. Misoprostol 400–600 μg sublingual or per-rectal may be an alternative in low-resource settings.

**Long-term Interventions to Prevent PPH**

The etiology of PPH can be traced to as early as the birth of a girl child. A girl enters puberty and later pregnancy with chronic anemia, ill health and malnourishment. These problems are aggravated by early marriage, frequent pregnancies, unsupervised antenatal and intranatal period. The following measures are required:

- Care of the girl child by providing a healthy environment for the overall development and avoiding early marriage.
- Care during pregnancy and delivery: Iron and folic acid supplements in antenatal period, detection and treatment of anemia, identifying high-risk pregnancies and early referral to tertiary center. Supervised delivery of high-risk pregnancies by senior obstetrician with active management of third stage of labor. Continuous vigilance in immediate postdelivery period “the fourth stage of labor” is essential.
- Protocol for the management of PPH should be standardized in each hospital and the labor room staff should be fully trained for this obstetrical emergency. Regular “fire drills” should be conducted for the same. The hospital should also have regular internal audits to improve outcome in PPH.
- Contraceptive advice, treatment of anemia if present and health education in puerperal period.
- Social responsibility—Education to increase awareness of women’s health in society should be emphasized at all levels. It is important to sensitize each family about the importance of early decision and timely transport of all suspected cases of excess bleeding. Government and community-based programs, training of birth attendants, strengthening blood bank and transport facilities with involvement of mass media to reach out to all have an important role to play.

**Medicolegal Aspect**

It is important to realize that at times despite the best of medical expertise and resources available, death or serious morbidity cannot be averted. Hence an informed consent with time to time discussion of the status of the patient with her relatives is of paramount importance in all cases of PPH.

**CONCLUSION**

To conclude, early diagnosis, prompt intervention and management with availability of newer techniques has led to a reduction in maternal mortality due to PPH since our independence but further efforts are required to make each and every pregnancy safe. Preventive measures have a definitive role in management of PPH, the social aspect of which needs to be dealt with effectively.

Management of Postpartum Hemorrhage

39

INTRODUCTION

Puerperal pyrexia is defined as the rise of 1°F temperature on two occasions from day 2 to day 10 of delivery or abortion. The United States Joint Commission on Maternal Welfare and the World Health Organization (WHO) International Classification of Diseases (ICD-10) consider febrile morbidity when temperature is greater than or equal to 38°C (100.4°F). We do not take first 24 hours into account, as quite often there is transient pyrexia due to physical strain of labor.

Puerperal sepsis is defined as infection of genital tract which occurs as a complication of delivery. Although puerperium extends up to 42 days, it is the 1st week after delivery that is most critical. Puerperal sepsis is also known as puerperal infection or child bed fever. A WHO technical working group on “The Prevention and Management of Puerperal Infections” in 1992 defined following definition of puerperal sepsis:

- Pelvic pain
- Fever
- Abnormal vaginal discharge, i.e. pus
- Abnormal smell/foul odor of discharge
- Delay in involution of uterus (< 2 cm/day during the first 8 days).

At the same time, WHO technical working group considered that puerperal infections is a more general term than puerperal sepsis, and includes not only infections due to sepsis, but also all extragenital infections and incidental infections.

Maternal mortality is one of the major public health problems challenging the medical community, especially in the developing countries. WHO recently estimated that 585,000 maternal deaths occur annually, 99% of those are in the developing world.

The United Nations Population Fund (UNFPA) in its latest update (1998-99) reported 15% of the maternal mortality which was due to puerperal sepsis and that it was the second direct cause of maternal mortality. WHO also reported maternal mortality as 15% due to puerperal sepsis.

Fortunately, it is declining with modern obstetric care. Chhabra et al. 2005 from Rural Medical Institute, India, reported decline in maternal mortality due to puerperal sepsis to 10% in the last 5 years from 35% in earlier years. However, it is still a major health problem in the developing world, and has worsened with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) infection. In rural India, maternal mortality continues to be high and it is different in different areas as shown in Table 1.

HISTORICAL ASPECT

Looking backward is always educative and it helps one to understand the condition better. In the 5th century BC, it was described by the Hippocrates as a serious complication of childbirth. By AD 200, Celsus and Galen had written in the support of the theories of Hippocrates. It was only in late 1,500s that lochial putrefaction or uterine inflammation was suspected as the cause of childbed fever. In 1659, Willis wrote on the subject of febrile puerperium, although the English term “puerperal fever” was probably first employed by Strother in 1716.
In the Modern Era, many individuals have contributed to its knowledge.

- In 1773, Charles White of Manchester suggested isolation of all cases. He postulated *Stagnation of Lochia* as a cause of fever.
- In 1843, Oliver Wendell Holmes presented to Boston Society, his study of puerperal fever. He blamed lack of precautions on the part of Doctors and Nurses as a cause of this condition.
- In 1861, Semmelweis of Vienna, linked it to Medical Students coming from postmortem room. He suggested washing hands before entering the labor room. He was ridiculed and later dismissed from his post (Fig. 1).
- Later in 1867, Lister’s Teaching of Antisepsis was known and Louis Pasteur’s development of Bacteriology was universally accepted and the whole concept of puerperal sepsis changed. Semmelweis by that time had suffered a nervous breakdown and died a miserable death on the streets of Vienna. But what he did not get in life, he got in death. He was now acclaimed to be a hero of all mothers and his contribution to midwifery was acknowledged. There is now a Museum in his home in Budapest and a monument to Mother and Child in his garden.

However, to practitioners of ancient Indian medicine, the art of asepsis was known even 2000 years ago. Charak, the famous Ayurvedic physician has reported about aseptic precautions in Labor Ward in his book “Charak-Samhita Sharirstan”, Chapter 8.3 and Shushrut in his book “Shushrut Samhita” has reported isolation of the parturient for 40 days to prevent infection.

### PREDISPOSING FACTORS FOR THE DEVELOPMENT OF PUERPERAL SEPSIS

It is generally considered that pelvic infections are common among women of poor socioeconomic status compared with upper or middle class women, but the precise reason is unclear. Factors responsible for predisposing puerperal sepsis are listed in Table 2.

In 1998, Dare et al.\(^1\)\(^3\) reported that predisposing factors associated with puerperal sepsis were anemia in pregnancy (69.2%), prolonged labor (65.7%), frequent vaginal examinations in labor (50.7%) and premature rupture of membranes (PROM) (31.5%).

During the last few years, a growing body of evidence suggests that the single most important risk factor for puerperal sepsis is cesarean section.\(^1\)\(^4\)\(^,\)\(^1\)\(^5\)

If one or more causes are present in a case, this forms a high-risk case. In such a case, prophylactic treatment to prevent major infection is justified. If possible, such cases should be transferred to suitable center at the earliest sign of infection.

Puerperal sepsis may be mild or severe. Severe sepsis may be in the form of:
- Pelvic cellulitis
- Adnexal masses

**SEPTICEMIA AND SEPTIC SHOCK**

Septicemia and septic shock occur late and one must diagnose before this stage is reached. However, one still sees cases admitted in septic shock. The following investigations need to be done:

- Hemoglobin percentage (Hb%), white blood cell (WBC): total and differential, platelets, erythrocyte sedimentation rate (ESR)
- Serum HIV after pretest counseling
- Swab culture-antibiotic sensitivity
- Blood culture and sensitivity (C/S)
- Urine routine and C/S
- X-ray of chest and abdomen in erect posture
- Ultrasoundography (USG) scan of whole abdomen
  - Color Doppler, if indicated
- Computed tomography (CT) scan, magnetic resonance imaging (MRI) if indicated
- Exploration of uterus/curettage, if needed biopsy
- USG-guided aspiration of a mass

All facilities may not be available everywhere; hence, whatever possible should be done. Clinical judgment, close observation and consultation with other colleagues sometimes can be more valuable than mere laboratory data.

Eschenbach et al. studied the endometrial isolates from 51 patients of puerperal sepsis in 1986. The results are as follows in Table 3.

In 1998, American College of Obstetricians and Gynecologists reported the bacteria commonly responsible for female genital infections as follows in Table 4.

It is obvious that one has to deal with mixed bacterial flora. Aerobes and anaerobes are likely and one must anticipate polymicrobial disease whether cultures are possible or not.

In 1988, Purwar et al. reported 68 cases of sepsis, out of which 77% were due to obstetrical sepsis. From the cervical swab culture aerobes were isolated in 75% while anaerobes in 1.5% and both aerobes and anaerobes in 18%. *E. coli*...
Klebsiella, Pseudomonas, Peptostreptococcus and Bacteroides were the most commonly isolated organisms. They reported excellent results with clindamycin and metronidazole.

Sometimes the cause of fever in parturient is not easily found, one must entertain other causes which may be non-gynecological/obstetric causes.

DIFFERENTIAL DIAGNOSIS OF PERSISTENT FEVER

- Pelvic infections
- Breast lesions
- Urinary tract infections
- Resistant organisms
- Nongenital cause such as tooth abscess, malaria respiratory infection
- Tuberculosis, very common in India
- Drug reactions
- Inadequate treatment or noncompliance of a patient who is treated at home.

It is a great feat of nature that the products of conception are kept sterile. This is achieved by several means. One of the important means is amniotic fluid which has antibacterial activity. It prevents the growth of microorganisms in vitro and in vivo. Appelbaum et al. studied antibacterial activity in the third trimester and found that it was not uniform in all races. In Caucasians, 76% had antibacterial activity whereas:
  - Indians had only 52%
  - Africans had only 33%.

The amniotic fluid components causing antimicrobial activity are several enzymes like lysozyme, peroxidases, transferrins, B lysins, etc.

It was Kitzmiller who suggested that antibacterial activity was related to maternal nutrition. It is reported that transferrins, which increased in iron-deficiency anemia has significant antibacterial action.

Vaginitis in pregnancy is of great significance according to Krohn et al. 1999. It can cause preterm labor, PROM, chorioamnionitis, neonatal infection and postpartum endometritis. In 2000, Schrag et al. reported maternal mortality following vaginitis (1 in 345 cases). Proper screening for infection is advisable. It is necessary to institute proper antibiotic therapy and reduce the risks. Rarely, infection can occur in the intranatal period without the rupture of membranes and without the onset of labor. If it happens, then there will be premature onset of labor. Infection is more likely to occur after the onset of labor and more so after the rupture of membrane. One of the leading causes of intranatal sepsis is preterm PROM (PPROM). Mother’s health is more important than fetal outcome. However, conservative treatment is advised till adequate fetal maturity is reached. One has to watch carefully for signs and symptoms of infection. At the earliest sign of infection, one must intervene and conduct safe delivery.

**PUERPERAL SEPSIS**

**Investigations**

- Hb%, WBC total and differential, platelets, ESR
- Swab and culture: From the cervix and upper vagina for aerobic and anaerobic cultures
- Blood culture: Taken at peak of temperature in case of septicemia
- Urine analysis and culture: Midstream or catheter specimen

**Prevention of Puerperal Sepsis**

**Antenatal Prevention**

- Proper diet, vitamins and minerals
- Anemia and diabetes should be treated
- Avoid sexual intercourse late in pregnancy
- Prophylactic antibiotics in presence of predisposing factors

**Intranatal Prevention**

- Strict aseptic and antiseptic measures for the patient, attendants and instruments
- Minimize vaginal examinations
- Avoid bleeding and excessive blood loss should be replaced
- Lacerations should be properly sutured immediately
- Prophylactic antibiotics in presence of predisposing factors

Most antibiotics cross the placental barrier but cord blood levels are 50–70% of maternal levels. One has to balance the toxic reactions to the fetus. However, it is believed that chemoprophylaxis will prevent sepsis neonatorum.
Postnatal Prevention

- Maintenance of aseptic precautions
- Care of the perineal or abdominal wounds
- Minimize visitors and keep away who are infected
- Early isolation of cases of puerperal sepsis

Treatment of Puerperal Sepsis

General Treatment

- Isolation in a separate room or fever hospital
- Diet: Light diet rich in vitamins and minerals with plenty of fluids
- Supportive treatment: Restoration of fluid and electrolyte balance, correction of anemia
- Symptomatic treatment:
  - Analgesics
  - Antipyretics cold compression and hot fermentation
- Observations: Pulse, temperature, blood pressure, vaginal bleeding, lochia, manifestations of deep vein thrombosis (DVT)

In 1999, West et al. reported that vitamin A supplementation in women may have reduced maternal mortality by 40% in a Nepalese community and Nurdiati reported 50% reduction in puerperal fever in Indonesian community.

Antimicrobial Therapy

Antimicrobial therapy is the mainstay in the treatment of puerperal sepsis. Parenteral use is imperative and oral medication has no place. Treatment is aimed at polymicrobial mixed flora. The following are the options:

- Multiagent:
  - Penicillin and gentamycin
  - Clindamycin and gentamycin
  - Ampicillin, gentamicin and metronidazole
  - Clindamycin and aztreonam
  - Clindamycin and second-generation cephalosporins:
    - Preferred in renal insufficiency
  - Azithromycin
- Single agent:
  - Cephalosporins:
    - Cefoxitin
    - Cefoperazone
    - Cefotaxime

Any of these should be started immediately and later, one can review and revise the therapy:

- When C/S report is ready
- No response in 72 hours, antibiotic therapy may be changed
- If toxicity appears, change is necessary.

One must check daily:

- WBC, urine albumin and creatinine
- Adequate hydration and urine output should be ensured
- Hepatotoxicity and nephrotoxicity is a possibility with high dosage of medication.

Surgical Treatment

- In case of infected perineal wound, stitches have to be removed to facilitate drainage of pus
- Infected retained products should be removed under cover of antibiotics by exploration of uterine cavity
- Pelvic abscess should be drained by posterior colpotomy

It is very difficult to decide when surgical interference by exploratory laparotomy should be undertaken in puerperal sepsis. The following are the guidelines:

- If the diagnosis is in doubt
- Evidence of free fluid or masses in the abdomen
- Hemorrhage, recurrent, from a soft, flaccid uterus
- Ovarian vein thrombosis
- No response to medical treatment.

Sequelae of Puerperal Sepsis

In the absence of antibiotic treatment or in the more severe cases, puerperal sepsis may be complicated by chronic pelvic pain, pelvic inflammatory diseases and secondary infertility. The more severe cases are responsible for the high rates of maternal mortality, i.e. about 15%, especially in developing countries.

There are a few specific and interesting forms of puerperal infections. These are phlegmasia alba dolens or deep vein thrombosis (DVT), clostridial gas gangrene and necrotizing fasciitis (Fig. 2).
**Phlegmasia Alba Dolens**

Phlegmasia alba dolens is also known as milk leg. It is classical puerperal thrombophlebitis diagnosed when patient, who has delivered recently, complains of severe pain and edema of the leg and thigh. It is abrupt in onset and may be unilateral. Usually deep veins from foot to iliofemoral are involved. There is also reflex arterial spasm causing the limb to be pale and cold with diminished pulsation.

Predisposing causes include:

- Use of obstetric cholestasis (OC) in the pre-pregnancy stage
- Stasis, no ambulation
- Varicose veins.

It is diagnosed clinically. When facilities exists, color Doppler would be useful. DVT is to be managed by immediate hospitalization. Treatment includes:

- Heparin IV
- Rest
- Analgesics
- Antibiotics.

One must watch for pulmonary emboli, diagnosed by a triad of symptoms, namely hemoptysis, tachypnea, and chest pain. Thrombophlebitis and phlebothrombosis have to be differentiated. Williams\(^\text{27}\) reported that 10% of all maternal deaths were due to pulmonary emboli, following DVT.

**Clostridial Gas Gangrene**

Gas gangrene is a fulminant infection caused by *Clostridium perfringens* in 60–80% of cases. Clinically, it presents with a sudden onset of severe pain. On examination, there are bullae and a diagnostic crepitus. The tissue has a bronzed look. Patient is usually in septic shock. Treatment consists of giving 20 million units of penicillin-G in divided doses. Polyvalent antitoxin is to be given at the earliest. In difficult cases, the use of hyperbaric oxygen chambers is recommended.

When a case of gas gangrene occurs it is important to isolate the case, close down routine surgery and thoroughly fumigate the operation theater.

**Necrotizing Fasciitis**

Necrotizing fasciitis is an uncommon, rapidly progressive, severe infection involving perineal, vaginal tissues and abdominal incisions in Cesarean section. There is necrosis of fascial lining, but muscles are not affected (Figs 3A and B). It is associated with very high mortality. Usually, it is synergistic polymicrobial infection that occurs in patients with coexisting factors predisposing them to bacterial inoculation and the spread of infection. In 1996, McHenry et al.\(^\text{28}\) reported the possible role of increase in bacterial virulence and the immunological changes of pregnancy as potential predisposing factors in the development of necrotizing fasciitis. Owen and Andrews (1994) reported diabetes hypertension and obesity as risk factors for this condition. Clinically, it presents as severe edema, extending to thighs, buttocks and abdominal wall. Surgery in the form of debridement and drainage is necessary. In 1980, Gibbs\(^\text{4}\) described 19 cases when early intervention was carried out; only one patient was lost whereas in cases when intervention was delayed more than 6 days, 8 cases were lost. Hence, early diagnosis, surgical debridement, antibiotics and intensive care units (ICU) are necessary for successful treatment of this infection (Urschel, 1999).\(^\text{29}\)

It is best to involve a general surgeon and a physician with ICU facilities. Good teamwork is essential. Patient should be transferred by a flying squad to the nearest tertiary care center (Fig. 4).
CONCLUSION

Prevention is better than cure. It is of utmost significance in this condition.

- Health education programs must emphasize the early signs and symptoms of the common postpartum complications and stress the importance of seeking professional help timely.
- Continuing medical education programs on perinatal care for doctors and midwives; emphasis on the early signs and symptoms, correct management and the referral protocols for puerperal sepsis.
- Prophylactic antibiotics cover for all complicated deliveries and abortions are worth considering.
- Encourage hospital deliveries. Infection is most likely in domiciliary midwifery.
- Minimum 72 hours postnatal stay. This will eliminate the risk of thrombophlebitis and severe sepsis.
- Low dose of vitamin A given during second and third trimester of pregnancy substantially reduces the risk of postpartum infection in population of vitamin A deficient women.
- Special management of high-risk cases those with predisposing causes. The prevalence of puerperal sepsis is likely to rise in coming years, as the AIDS epidemic progresses further.
- More obstetric ICUs are needed, especially, at District level.
- Teamwork is necessary for successful outcome.
  Primary-secondary-tertiary care should have close links and good communication and transport facilities. This is an opportunity for obstetricians to work in close cooperation with surgeons and physicians.

REFERENCES

Breastfeeding Promotion

INTRODUCTION

Mothers’ milk is the ideal and complete food for the first 6 months of life. Breastfeeding saves more lives than immunization and oral rehydration solution (ORS) combined. More than 2.4 million child deaths occur in India each year; two-thirds of these are related to inappropriate infant feeding practices. Child-survival data, Lancet 2003 recommends promotion of exclusive breastfeeding in the first 6 months as the single most effective intervention to reduce under-5 mortality by 13–15%.

A nonbreastfed infant is 14 times more likely to die of diarrhea, three times more likely to die of respiratory infection, and twice as likely to die of other infections than an exclusively breastfed child. Death among newborns not suckled at the breast is at least five times higher than among those who receive colostrum and mother’s milk.

Does Breastfeeding Need to be Promoted?

Malnutrition has been responsible, directly or indirectly for 60% of 109 million deaths among children, two-thirds being associated with inappropriate feeding practices. Research continues to reveal evidence of the value of breastfeeding and breast milk.

There is a misconception in the minds of the majority that nearly every Indian baby is breastfed and hence the hesitation to accept promotion of breastfeeding as a major issue. However, a study from an under-5-clinic in a public hospital in Mumbai revealed that only 64% mothers exclusively breastfed their babies at birth, 17% near totally breastfed, while 19% partially breastfed their babies. This and other similar studies give lie to the myth that breastfeeding is widely prevalent in our country.

Advantages of Breastfeeding

There is strong evidence to show that breastfeeding decreases the incidence and/or severity of diarrhea, lower respiratory infection, otitis media, bacteremia, bacterial meningitis, botulism, urinary tract infection and necrotizing enterocolitis. A number of studies show a possible protective effect of human milk feeding against sudden infant death syndrome, insulin dependent diabetes mellitus (IDDM), Crohn’s disease, ulcerative colitis, lymphoma, allergic diseases and other chronic diseases.

Health benefits of breastfeeding can last a lifetime. Children and adults who were breastfed are less likely to develop asthma, IDDM and certain cancers (leukemia, lymphoma and Hodgkin’s disease). Babies who were breastfed may be less likely to become obese later in life.

A child’s first 3 years are the most critical in brain development. Optimal nutrition starts in utero and continues with breastfeeding, often called the “4th trimester.” A recent long-term study found breastfed children had statistically significant increases in intelligence quotient (IQ), reading, comprehension, mathematical ability and scholastic ability. Breastfeeding has also been related to possible enhancement of cognitive development, particularly in preterm babies.

Breastfeeding is the ideal way to begin, establish and nurture a close bond between mother and infant. The infant learns trust in early human closeness as well as cooperation with another human being. Mothers who breastfed successfully often have an increased sense of self worth and empowerment. Breastfed infants are rarely, if ever, victims of child abuse and neglect.

Exclusive breastfeeding reduces the chances of a next pregnancy for 6 months. As the fat accumulated during pregnancy is used in milk production, prolonged
breastfeeding can help mothers to return to their previous weight. Breastfeeding mothers have less risk of breast cancer and ovarian cancer, decreased insulin requirements in diabetics, stabilizing maternal endometriosis and less risk of postpartum hemorrhage, endometrial cancer and osteoporosis.

Breastfeeding not only saves lives but saves the family enormous finance, which is of particular importance in a country like ours.

**Who Should Promote Breastfeeding?**

Promoting breastfeeding is a subtle art with a blend of thoughtful suggestions and conveying accurate information over a period of time. There is perhaps no better time to do this than during the antenatal period where a breast examination should be made a routine. The 2nd trimester is considered to be a good time for breastfeeding advice as this is the time that the mother feels the baby move and is hence more receptive. Labor should be considered complete only if the mother feels the baby move and is hence more receptive. Labor should be considered complete only when breastfeeding has been successfully established.

**Different Compositions of Milk**

Breast milk has the unique property of being able to cater to the needs of the baby, depending on its maturity, be it a full term or preterm.

The various types of milk are:

- **Colostrum:** Colostrum is the thick, sticky, yellowish milk secreted in the first 72 hours after delivery. It is all that the baby needs for the first few days. It contains large quantities of protective substances.
- **Transition milk:** Transition milk is the milk seen after 72 hours of delivery and has lesser immunoglobulin and protein, but more fat and sugar content than colostrum. Exclusive breastfeeding of colostrum and transition milk minimizes infection related neonatal deaths in maternity care facilities.
- **Mature milk:** Mature milk is composed of fore-milk and hind-milk. Fore-milk comes at the start of the feed; is watery; has low fat, high lactose sugar, proteins, vitamins and minerals. It satisfies the babies’ thirst. Hind-milk comes later in the feed, is richer in fat and supplies energy. It has a satiety effect.
- **Preterm milk:** Preterm milk is the milk produced by a woman who delivers preterm and has more protein, minerals, immunoglobulins and lactoferrin.

**The First Feed—Early Initiation**

Early initiation of breastfeeding is the key to establishing a good milk supply. It is begun when rooming-in is practiced, i.e. the mother has the baby with her day and night.

Breastfeeding should begin as soon as possible after birth, usually within the 1st hour. The newborn infant should remain with the mother throughout the recovery period, except under special circumstances. Newborns should be nursed whenever they show signs of hunger, such as increased alertness or activity, mouthing or rooting; approximately 8–12 times every 24 hours until satiety, usually 10–15 minutes on each breast. No supplements should be given to breastfeeding newborns, unless a medical indication exists.

**How to Feed? Which Position?**

There are several positions in which a mother can breastfeed her baby. However, the best position is one in which both the mother and the baby are comfortable. The important principles of positioning are:

- The baby’s whole body should face the mother and be close to her, with the head and neck in a straight line facing the breast.
- The baby should be well attached to the breast, i.e. the baby’s mouth should be wide open with the chin touching the breast, the lower lip curled outward, the areola not being visualized and the mother not feeling pain in the nipple while feeding.

**Lactation Failure—Reality or Myth?**

Inadequate milk production is an important reason for resorting to top feeds. The reasons why a mother feels that she has insufficient milk are because the baby cries often, wakes up frequently, demands frequent feeds or is irritable. The common reasons for this so called lactation failure are giving prelacteal feeds, discarding colostrum and keeping mothers and babies separately.

The mother should be told that an exclusively breastfed baby showing a weight gain of 500–1,000 g/month and passing urine at least 6–8 times/day is definitely getting enough milk. The role of galactogogues is limited. The best galactagogue is a baby suckling at the breast in a correct position, frequently and for an adequate duration.

**SPECIAL ISSUES**

**Human Immunodeficiency Virus and Breastfeeding**

Human immunodeficiency virus (HIV) passes via breastfeeding to about one out of seven infants born to HIV-infected women. Analysis of available data shows that the maximum risk of transmission is during labor. However, in many situations where there is a high prevalence of HIV, the lack of breastfeeding is associated with a three- to fivefold increase in mortality. A research has highlighted a lower risk of HIV transmission with exclusive breastfeeding by HIV positive mothers (4% risk), compared to mixed feeding (10–40% risk). This is of particular importance in developing countries where infant formula is not widely available or safe to prepare.
Conditions that are not Contraindications to Breastfeeding\textsuperscript{17,18}

Certain conditions have been shown to be compatible with breastfeeding: such as infants born to mothers who are hepatitis B surface antigen–positive, or infected with hepatitis C virus, mothers who are febrile, have been exposed to low-level environmental chemical agents and mothers who are seropositive carriers of cytomegalovirus (CMV) (not recent converters if the infant is term).

*Tobacco smoking*\textsuperscript{19} by mothers is not a contraindication to breastfeeding, but tobacco-using mothers should avoid smoking within the home and to make every effort to wean themselves from tobacco. Breastfeeding mothers should avoid the use of *alcoholic beverages*, because alcohol is concentrated in breast milk and its use can inhibit milk production.

Women who have had breast surgery, such as breast enlargement or reduction, should discuss breastfeeding with their healthcare providers. Most will be able to breastfeed, though some may have problems, such as not being able to produce enough milk.

Contraindications to Breastfeeding\textsuperscript{12,17,18}

- Infants with classic galactosemia
- Mothers with untreated pulmonary tuberculosis
- If the mother is taking certain medications that suppress the immune system; uses potentially harmful substances such as cocaine, heroin and amphetamines; or has had unusually excessive exposure to heavy metals.

Medications and Breastfeeding\textsuperscript{14,20}

The vast majority of medicines are compatible with breastfeeding, but there are some that might be passed onto the child through the milk. While small amounts of many medications do enter breast milk, most do not harm the baby. However, a woman always should check with her and her baby’s healthcare provider before taking a medication (including over-the-counter and herbal preparations). The healthcare provider may switch a woman to a safer medication or may advise her to take her medication soon after breastfeeding, so most of the medication will be out of her system before the next feeding.

**The Role of Federation of Obstetric and Gynaecological Societies of India\textsuperscript{1}**

Besides declaring 1997 as the “Federation of Obstetric and Gynaecological Societies of India (FOGSI) Breastfeeding Promotion Year” the Federation:

- Printed slogans on all FOGSI envelopes and the letterhead of the Federation to propagate breastfeeding
- Released one issue of the Indian Journal of Obstetrics and Gynecology devoted to the many aspects of breastfeeding and its correct practice
- Released a booklet on “Breastfeeding Your Baby” at the World Congress on Labor and Delivery
- Developed a 3-hour program in the form of lectures and videotape which can be organized at all the societies
- Conducted workshops on safe motherhood which also emphasize breastfeeding
- Held training programs on lactation management.

Role of Employers\textsuperscript{14}

Employed mothers form an important group today as more women are joining the work force. Exclusive breastfeeding poses a special problem to women who work outside the home. An employer needs only to make minor accommodations to allow employees to breastfeed their babies. Working mothers should be given extended maternity leave for 6 months if possible. Crèche if available at the workplace should be used. Working mothers should also be taught and asked to express milk. This milk can be stored for 24 hours in a refrigerator. Once a mother returns from work she can continue to feed the baby when at home or during holidays. Expressed milk can be fed to the baby while she is at work.

The Role of the Judiciary\textsuperscript{14,21}

To protect infant health, India became one of the few countries in Asia to fully implement the International Code of Marketing of Breastmilk Substitutes with the enactment of the infant milk substitutes, feeding bottles and infant foods (Regulation of Production, Supply and Distribution) Act, 1992 (41 of 1992) (hereinafter referred to as “the IMS Act”). The objective of the IMS Act is to protect breastfeeding from commercial promotion, and thereby prevent malnutrition and deaths in infants and young children. The IMS Act controls marketing practices of baby food manufacturers.\textsuperscript{3}

Role of Voluntary Organizations

Various voluntary organizations like Breastfeeding Promotion Network of India (BPNI) and Association for Consumer Action on Safety and Health (ACASH) have already taken up the cause of fighting the menace of commercial foods by filing criminal cases against companies violating the IMS Act.

Role of Government/Media\textsuperscript{21}

The role of the government and policy makers does not end with the enactment of the law. They should take some bold steps to implement the policies and provisions of the act. The Health Ministry should start promoting and supporting breastfeeding through TV and radio channels. We see
National and International Action for Support of Breastfeeding\textsuperscript{14,22,23}

Alarmed by the harmful trends in infant feeding practice, international organizations stepped up their efforts to promote the breastfeeding culture. An important starting point is the joint WHO/UNICEF booklet—“Promoting, protecting and supporting breastfeeding”, in 1989.

This was followed by the Baby Friendly Hospital Initiative (BFHI) with its “10 steps to successful breastfeeding” in June 1991.

Baby Friendly Hospital Initiative was initiated in India in the Metropolitan cities and then spread to the whole country. The National Task Force comprises of representatives from Government of India (GOI), United Nations International Children’s Emergency Fund (UNICEF) and World Health Organization (WHO) along with professional bodies such as FOGSI, Indian Medical Association (IMA), Indian Academy of Pediatrics (IAP), Trained Nurses Association of India (TNAI), etc. with a secretariat located in the IMA headquarters in Delhi.

The Breastfeeding Promotion Network of India and the World Alliance for Breastfeeding Action (WABA) are national and global network of organizations and individuals who believe that breastfeeding is the right of all children and mothers and devote themselves to protect, promote and support that right. Since 1992, World Breastfeeding Week has been celebrated between 1st August and 7th August. The aims are protecting, promoting and supporting the mothers and babies by reinstating breastfeeding as an integral part of women’s reproductive cycle and health, creating awareness of women’s right to humane and noninvasive birthing practices and promoting a global initiative for support for breastfeeding as one way to strengthen the support for mothers.

CONCLUSION

Breastfeeding was the best, is the best and will remain the best as far as infant feeding is concerned. Extensive research shows that human milk and breastfeeding provide compelling advantages to infants, mothers, families and society, including nutritional, developmental, health, immunologic, psychologic, social, economic and environmental benefits. Hence, it deserves to be promoted through all possible means and avenues.

REFERENCES

A Few Observations

- During the postpartum period about 85% of women (10–15% to a severe extent) suffer from some kind of behavioral or mood disturbance.¹
- Puerperal psychosis is associated with 4% infanticide and high incidence of suicide.
- A majority of it were supposed to be suffering from schizophrenia whereas the modern look is that most of them are suffering from a type of mood disorder.
- The postpartum period has been identified as a time of increased risk for the development of psychiatric illness in women and this comes from observation that psychiatric admissions peak during the first 3 months after delivery. Hence a thorough understanding of this topic is must for a student of obstetrics.

Since 1858, when Marce² wrote a treatise on puerperal psychosis, the problems that some women experience in the postpartum period have been the subject of much confusion. These problems affect not only the woman but also her spouse, previously born children and new born baby. For 9 whole months preceding the baby’s birth, the mother to be prepared herself for the new arrival. And when the day finally comes, looking at her baby, holding him in her arms, she goes through a wide range of emotions, from relief to joy and exhilaration, to fear, uncertainty and anxiety. For many or most mothers, giving birth is one of the supreme moments of their lives.

Newly delivered mothers have to face a number of challenges, including the following:³
- **Physical exhaustion**: Due to prolonged labor pains
- **Multiple responsibilities of mother, housekeeper, and wife**
- **Breastfeeding**: Anxiety associated with its initiation
- **Insomnia**
- **Recovery of normal figure and attractiveness**
- **Loss of libido** and associated stress with spouse

With this background of rapid biological, social, and emotional transition, it is not surprising that a wide variety of psychiatric disorders occur; indeed the psychiatric complications of childbirth are more numerous and complex than in any other human situation.

The first description of postpartum disorder comes from Hippocrates who described mania related to lactation. There was virtually no mention of puerperal mental illness until the 1700s and 1800s, when case reports of “puerperal insanity” began to appear in the French and German medical literature.⁴ Since the first clear description by Osiander in 1797 and the authoritative accounts by Esquirol in 1818 and Marcé in 1858, there has been a long-standing controversy about their place in the nosology of the psychoses. In 1960 B Pitt described an atypical depression, later called as “Maternity Blues” that affected mothers soon after childbirth.⁵ It was relatively mild and short lived. The concept of a more severe form of nonpsychotic depressive illness (i.e. postpartum depression) emerged during the 1970s.

**ETIOPATHOLOGY**

It was Victor Louis Marce in 1858, who first suggested, long before the emergence of the modern field of endocrinology, that a physiological transition occurring after delivery may play an important role in the pathogenesis of puerperal illness. Other investigators have emphasized the importance of psychosocial factors and biological vulnerability to psychiatric illness during the puerperium. The factors which can be considered are:
- Demographic and psychosocial factors
- Biological factors
- Past psychiatric illness
Demographic and Psychosocial Factors

Experts are not exactly sure why postpartum psychosis happens. The possible reasons or contributing factors include a lack of social and emotional support; a low sense of self-esteem due to a woman’s postpartum appearance; feeling inadequate as a mother; feeling isolated and alone; having financial problems; and undergoing a major life change. One of the most consistent findings is that postpartum depressive illness is more common in women who report marital dissatisfaction or inadequate social supports.

There is little consistent evidence to suggest that any particular demographic factor including age, marital status, parity, education level, socioeconomic status or nutritional status, places a woman at increased risk for puerperal psychiatric illness. Some studies have found a relationship between adolescent mothers and risk for puerperal illness. Obstetrical complications (e.g. prolonged labor, cesarean section, stillbirths) may increase the likelihood of postpartum psychosis.

Biological Factors

During the postpartum period a rapid shift in the hormonal environment occurs in comparison to the pregnancy state. The blood levels of various hormones especially estrogen and progesterone and cortisol fall dramatically within the first 48 hours after delivery. Many investigators have proposed a role for these hormones in the emergence of a mood disorder during the postpartum period. It has been observed by some studies that postpartum estrogen deficiency and declining level of progesterone may result in postpartum mood disturbance. It has been suggested by a beneficial effect of progesterone and or estrogen hormone replacement in the treatment of postpartum psychiatric illness. Thyroid levels can drop rapidly and 10% of women will develop clinical hypothyroidism postpartum. Hypothyroidism may produce psychiatric symptoms nearly similar to depression.

Past Psychiatric Illness

There is a well-defined association between all types of postpartum psychiatric illness and a personal history of mood disorder. Women with a history of postpartum psychosis are at highest risk. The risk of experiencing an episode of postpartum psychiatric illness increased up to 70% in women who have had one episode of puerperal psychosis and as high as 30% in women who have had postpartum depression. A relapse rate of 20–50% has been noticed in women with history of bipolar disorders during the postpartum period. Women with histories of mild to moderate affective illness who remain euthymic during pregnancy are probably at lower risk for postpartum depression.

Reproductive Hormones

Reproductive hormonal fluctuations modulate central affective function. Estrogen modulated N-methyl-D-aspartate receptors induce the formation of new synapses. This observation suggests a pivotal role for estrogen in the plasticity of the nervous system.

Exposure to and withdrawal from the neurosteroidal metabolite of progesterone, allopregnanolone, influence a principal regulator of cognitive function and affect, the gamma-aminobutyric acid (GABA)-A receptor. Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine and paroxetine, increased brain concentrations of allopregnanolone in rats, which may explain their antidepressant efficacy in depressed patients mediated via GABAergic receptor activity. Additionally, the SSRI sertraline prevents postpartum depression while the tricycle antidepressant nortriptyline does not. This phenomenon may be explained by the fact that SSRIs increase brain levels of neuroactive steroids, which may decrease the risk for depression in the postpartum milieu.

Thyroid Hormones

Postpartum thyroid dysfunction occurs in 5–10% of women within 1 year following delivery and may predispose a woman to affective dysregulation. Simultaneous treatment of both the thyroid dysfunction and the affective disorder is usually essential for optimum treatment results.

CLINICAL PRESENTATIONS

Postpartum psychiatric illness is typically divided into three categories: (1) postpartum blues, (2) nonpsychotic postpartum depression (also called as neurotic depression in past) and (3) puerperal psychosis. It is helpful to conceptualize these disorders as existing along a continuum, as there may be significant overlap between these three diagnostic subtypes.

Postpartum Blues

Postpartum blues also called as “baby blues” are the most common mood disturbance, affecting an estimated 50–85% of women. Given how common this type of mood disturbance is, it may be more accurate to consider the blues as a normal experience following childbirth rather than a psychiatric illness. Rather than feelings of sadness, women with the blues more commonly report mood liability, tearfulness, anxiety or irritability. These symptoms typically peak on the fourth or fifth day after delivery and may last for a few hours or a few days, remitting spontaneously within 1–2 weeks. Only support and reassurance is sufficient for most of the cases as postpartum blues are usually mild in severity and
Postpartum Pinks

While “the blues” refers to mood lability (or changes in mood from happy to sad), some women experience mild elation, or “the pinks,” following childbirth; again, this elation lasts for a few hours to days until a more normal level of happiness returns.

Nonpsychotic Postpartum Depression

Postpartum depression occurs in 10–15% of women in the general population. Women at highest risk are those with a personal history of depression, or previous episode of postpartum depression. Typically, postpartum depression develops insidiously over the first 3 postpartum months, though it may have a more acute onset. Symptoms may include depressed mood, tearfulness, anhedonia (lack of pleasurable feelings), insomnia, fatigue, appetite disturbance, suicidal thoughts, and recurrent thoughts of death. Anxiety is prominent, including worries or obsessions about the infant’s health and well-being. The mother may have ambivalent or negative feelings toward the infant. She may also have intrusive and unpleasant fears or thoughts about harming the infant. Postpartum depression often interferes with the mother’s ability to care for herself or her child. It is advisable to screen all women for depression during the postpartum period. Severity of illness should guide treatment.

Other Neurotic Disorders

Phobias, anxiety states and obsessive compulsive disorders may also occur and interfere markedly with child care. A mother with a germ phobia, for example, may have great difficulty in washing nappies and become upset if her baby does not develop a precise routine. For some women with postpartum anxiety, the fear or anxiety is general, but for others the symptoms may relate to something more specific (i.e. bathing the baby, taking the baby out in the car, coping with grocery shopping) or the symptoms may focus solely on the child (i.e. is the baby feeding properly and breathing properly, is the woman competent as a mother and able to look after the baby). Between 4% and 15% of women experience anxiety following childbirth. Many mothers feel anxious, overwhelmed and scared following the birth of their baby. This is understandable given the changes involved in becoming a new parent. However, for some women the level of anxiety is so severe that it interferes with their daily lives, and represents a change in normal character and functioning. The treatment strategy is similar to that of nonpuerperal anxiety disorders.

Puerperal Psychosis

Puerperal psychosis is a psychiatric emergency that typically requires inpatient treatment. Most patients with puerperal psychosis suffer from bipolar disorder. Postpartum (or puerperal) psychosis usually develops symptom within the first 2–3 weeks after delivery. Postpartum psychosis symptoms usually appear quite suddenly; in 80% of cases, the psychosis occurs 3–14 days after a symptomfree period. Postpartum psychosis is the most severe and rare form of postpartum mood disorder, with rates of 1–2 per 1,000 deliveries. Puerperal psychosis resembles a rapidly evolving affective psychosis with manic, depressive, or mixed features. The earliest signs are typically restlessness, irritability, insomnia and feelings of depression. Women with this disorder typically exhibit a rapidly shifting depressed or elated mood, disorientation or depersonalization, and disorganized behavior and excitement. Delusional beliefs often center on the infant and include delusions that the child may be defective or dying, that the infant has special powers. Auditory hallucinations that instruct the mother to harm or kill herself or her infant are sometimes reported. Cases of infanticide and suicide are rare but are a serious risk in women with postpartum psychosis. The symptoms of postpartum psychosis fluctuate rapidly, and a woman who was lucid and calm upon first interview can be suicidal and psychotic within a matter of hours.

INVESTIGATIONS AND DIAGNOSIS

The official classification of American Psychiatric Association [Diagnostic and Statistical Manual of Mental Disorders (DSM) IV] does not recognize postpartum psychiatric disorders as individual entity. According to DSM-IV, postpartum psychiatric disorders may be indicated with a postpartum onset specifier4 to the mood or schizophrenia disorder as the case may be. However, in WHO classification of International Classification of Diseases-10, these disorders are given a separate listing at code no. 099.3 and at F53. The British view postpartum psychiatric disorders as a distinct group whose etiology, clinical presentation and prognosis differ from those of nonpuerperal mental illnesses. In contrast, the American view is that the disorders are simply affective or schizophrenic episodes occurring postpartum.

Screening

Severe postpartum depression and psychosis are easily recognized; however, milder or more insidious forms of depressive illness are frequently missed. Even severe
depressive symptoms that arise during the puerperium may be dismissed by both patients and caregivers as normal or natural consequences of childbirth. Since it is difficult to reliably predict which women in the general population are likely to develop puerperal illness, it is advisable to screen all women for depression during the postpartum period. Screening for mood disorders during the postpartum period may, however, be more difficult than at other times. Many of the neurovegetative signs and symptoms characteristic of major depression (e.g., sleep and appetite disturbance, diminished libido, low energy) are also observed in nondepressed women during the acute puerperium. The Edinburgh Postnatal Depression Scale (EPDS) is a ten-item, self-rated questionnaire that has been used extensively for the detection of postpartum depression and has demonstrated satisfactory sensitivity and specificity in women during the postpartum period.\(^9\)

**DIFFERENTIAL DIAGNOSIS**

Various medical illnesses may mimic psychiatric illness during the postpartum period. Hypothyroidism is relatively common and may cause a constellation of symptoms resembling major depressive disorder. Women with a pre-existing psychiatric illness may experience exacerbation of symptoms during the puerperium. Furthermore, any psychiatric illnesses may emerge for the first time during the postpartum period. Schizophrenia or schizoaffective disorder, particularly when characterized by prominent positive symptomatology, may be difficult to distinguish from puerperal psychosis. A possibility of substance-induced mood disorder due to postanesthetic states, such as after cesarean section or meperidine-scopolamine analgesia should also be kept in mind.

**MANAGEMENT**

A clinician’s approach to the patient should be guided by the type and severity of the symptoms and the degree of functional impairment. However, before initiating psychiatric treatment, medical causes for mood disturbance (e.g., thyroid dysfunction, Sheehan’s syndrome) must be excluded. Initial evaluation should include a thorough history, physical examination, and routine laboratory tests.

**Postpartum Depression**

Milder forms of depression may respond to supportive psychotherapy. More severe depression may require pharmacological treatment. Non-pharmacological treatment strategies are useful for women with mild-to-moderate depressive symptoms. These modalities may be especially useful for mothers who are nursing and who wish to avoid taking medications.\(^9\) These may be used to address: role conflict, disturbed relationships with the husband and social supports, and interaction with the infant.

**Pharmacological Therapy**

Several studies have demonstrated the efficacy of antidepressant medications (e.g., fluoxetine, sertraline, venlafaxine) in the treatment of postpartum major depressive disorder. In all of these studies, standard antidepressant doses were effective and well-tolerated. The choice of an antidepressant drug should be guided by the patient’s prior response to antidepressant medication and a given medication’s adverse effect profile. The adjunctive use of a benzodiazepine may be very helpful. In women with severe postpartum illness, electroconvulsive therapy (ECT) should be considered early because it is safe and highly effective.

**Hormonal Therapy**

Some authors have suggested that progesterone is helpful in the management of postpartum depression. A study by Gregoire has suggested that estrogen alone (or possibly when used as an adjunct to an antidepressant agent) may be useful in the treatment of postpartum depression.\(^10\)

**Interpersonal Therapy**

Women with postpartum depression were 2–3 times more likely to recover when randomly assigned to 12 sessions of interpersonal therapy (IPT) compared to the wait list control. In a group intervention study based on IPT during pregnancy, Zlotnick et al. successfully prevented postpartum depression in at-risk women while 33% of the treatment as usual control group developed major depressive disorder.

**Electroconvulsive Therapy**

Electroconvulsive therapy administration is recommended as first-line treatment if psychotic symptoms are present and as an effective alternative to untreated depression in the peripartum period. However, uterine tocodynamometry and fetal cardiotocography monitoring to detect premature uterine activity and fetal arrhythmias are recommended precautions during ECT administration.

**Estrogen Therapy**

Endogenous estrogenic steroids exert both genomic and nongenomic activational effects on brain function. Gregoire et al. studied the antidepressive properties of transdermal estrogen (17β-estradiol) in 61 women with chronic treatment-resistant postpartum depression. The mean EPDS scores improved rapidly during the first month of treatment when compared with controls with an overall treatment effect of 4.38 points on the EPDS (95% CI, 1.89–6.87). Although sustained over 5 months, the estradiol antidepressant effect was confounded by the co-administration of antidepressant in half the population.

**Bright Light Therapy**

The effectiveness of bright light therapy for antepartum depression was provided in a small controlled trial. Ten pregnant women were randomized to 5 weeks of 7,000-lux box (active) or a 500-lux (placebo) box. At 10 weeks, there was significant treatment effect; phase advancement of melatonin circadian rhythm on measured salivary melatonin levels was correlated with the treatment effect.

**Essential Fatty Acids**

Hibbeln and Otto et al. demonstrated a significant association between low docosahexaenoic acid (DHA) levels, an ω-3 essential fatty acid, and the occurrence of postpartum depression. In an open-label trial of ω-3 essential fatty acid, seven depressed women at least 16-weeks-pregnant were prescribed between 0.93 g/day and 2.8 g/day of eicosapentaenoic and docosahexaenoic acid (EPA/DHA). Five of the seven patients experienced a decrease of greater than 40% on the EPDS scores which were more than 12 at the beginning of the study. This approach merits further studies because of its safety and tolerability.

**Acupuncture**

Manber et al. randomized 61 women to active acupuncture, valid control acupuncture that did not address depression symptoms and massage for 8 weeks. Responders were provided treatment until 10 weeks postpartum. The active acupuncture group achieved a 43.8% remission in symptoms compared with 21.1% in the control group and 31.6% in the massage group. This novel study provides preliminary efficacy data for acupuncture treatment in antepartum depression and warrants further trials.

**Prevention Trials in Postpartum Depression**

Women who have experienced postpartum depression have a 25% risk of recurrence with a subsequent pregnancy. Thus, women with a history of postpartum depression should be at a minimum closely monitored with established screening tools. Preventive pharmacotherapy should also be considered after delivery. Effective prophylaxis may require treatment for 6 months using the drug that previously provided a good response or from an SSRI. Following the treatment phase, a gradual taper of the antidepressant dose at a rate of 33% per week is recommended to prevent the onset of a discontinuation syndrome.

**Puerperal Psychosis**

There are no specific treatments. The first resource is sedation by neuroleptic agents, but these should be used with caution because of the risk of severe extrapyramidal side effects, including the neuroleptic malignant syndrome. It is usual to stop breastfeeding, although this may not be necessary because the infant receives only a minute dose of the neuroleptic and adverse effects have not been noted. Some have argued that postpartum psychosis is indistinguishable from a manic psychosis and should be treated similarly. Acute treatment includes a mood stabilizer in the form of lithium, valproic acid, carbamazepine in combination with antipsychotic medications and benzodiazepines. Short-term treatment with an antipsychotic medication as well as a mood stabilizer is appropriate. However, lithium may have adverse effects on breastfed infants. ECT is highly effective in all varieties of puerperal psychosis, including puerperal mania. Untreated puerperal psychosis is associated with increased risk of infanticide as high as 4% and extremely high risk for suicide. A maintenance treatment should be given to prevent relapses.

**Reproductive Toxicity of Antipsychotic Treatment**

The categorical format (A, B, C, D, X) of teratogenic risk as classified by the Food and Drug Administration is under revision. The sophistication of risk-benefit decision analysis has improved with the incorporation of multiple domains of reproductive toxicity. Intrauterine fetal death, morphological teratogenicity, growth impairment, neonatal toxicity and neurobehavioral teratogenicity represent these five domains.

**Intrauterine Death**

Intrauterine death is not associated with exposure to fluoxetine, sertraline, paroxetine, citalopram and fluvoxamine, venlafaxine, or tricyclic antidepressants.

**Morphological Teratogenicity**

Minor malformations (which by definition have no functional or cosmetic significance) have been reported after first trimester fluoxetine exposure. Major malformations have not been reported with tricyclics, the SSRIs, venlafaxine or the phenylpiperazine antidepressants, trazadone and nefazodone.

**Growth Impairment (Low-birth Weight, Small for Gestational Age Infants and Preterm Labor)**

In small cohort studies, comparable antenatal growth and birth weights occurred in infants exposed to tricyclics, newer SSRIs, venlafaxine, trazadone and nefazodone relative to nondepressed controls. In a study that involved 969 pregnant women, the mean birth weight in a specific pregnancy week was greater in infants of mothers who were on antidepressants compared with nondepressed controls. Chamber et al. reported significantly lower birth weights related to lower maternal weight gain after fluoxetine exposure in the third trimester.

---

**Essential Fatty Acids**

Hibbeln and Otto et al. demonstrated a significant association between low docosahexaenoic acid (DHA) levels, an ω-3 essential fatty acid, and the occurrence of postpartum depression. In an open-label trial of ω-3 essential fatty acid, seven depressed women at least 16-weeks-pregnant were prescribed between 0.93 g/day and 2.8 g/day of eicosapentaenoic and docosahexaenoic acid (EPA/DHA). Five of the seven patients experienced a decrease of greater than 40% on the EPDS scores which were more than 12 at the beginning of the study. This approach merits further studies because of its safety and tolerability.

**Acupuncture**

Manber et al. randomized 61 women to active acupuncture, valid control acupuncture that did not address depression symptoms and massage for 8 weeks. Responders were provided treatment until 10 weeks postpartum. The active acupuncture group achieved a 43.8% remission in symptoms compared with 21.1% in the control group and 31.6% in the massage group. This novel study provides preliminary efficacy data for acupuncture treatment in antepartum depression and warrants further trials.

**Prevention Trials in Postpartum Depression**

Women who have experienced postpartum depression have a 25% risk of recurrence with a subsequent pregnancy. Thus, women with a history of postpartum depression should be at a minimum closely monitored with established screening tools. Preventive pharmacotherapy should also be considered after delivery. Effective prophylaxis may require treatment for 6 months using the drug that previously provided a good response or from an SSRI. Following the treatment phase, a gradual taper of the antidepressant dose at a rate of 33% per week is recommended to prevent the onset of a discontinuation syndrome.

Minor malformations (which by definition have no functional or cosmetic significance) have been reported after first trimester fluoxetine exposure. Major malformations have not been reported with tricyclics, the SSRIs, venlafaxine or the phenylpiperazine antidepressants, trazadone and nefazodone.

**Growth Impairment (Low-birth Weight, Small for Gestational Age Infants and Preterm Labor)**

In small cohort studies, comparable antenatal growth and birth weights occurred in infants exposed to tricyclics, newer SSRIs, venlafaxine, trazadone and nefazodone relative to nondepressed controls. In a study that involved 969 pregnant women, the mean birth weight in a specific pregnancy week was greater in infants of mothers who were on antidepressants compared with nondepressed controls. Chamber et al. reported significantly lower birth weights related to lower maternal weight gain after fluoxetine exposure in the third trimester.
Simon et al. reported a twofold increased in preterm labor after SSRI exposure that was not limited to infants exposed late in pregnancy. However, they did not report the specific dosing or timing of treatment during pregnancy to justify the negative attributions to the SSRI exposure. Obstetrical factors were not excluded and depressive symptoms were not assessed directly. The active (state) effects of depression and the residual (trait) effects (changes in maternal physiology which remain even when the mother is asymptomatic) could affect pregnancy outcome negatively. Thus, the negative outcomes attributed to the SSRI may well have been related to either unremitting depression or the interaction of depression with SSRI exposure.

Chambers et al. also reported an increased risk for preterm birth (14.3%) in infants whose mothers took fluoxetine in the third trimester compared to infants whose mothers discontinued fluoxetine before the third trimester (4.1%) as well as controls (5.6%). Compared to a combined group of infants whose mothers took paroxetine during the first and second trimesters as well as controls, increased preterm birth in infants whose mothers took paroxetine in the third trimester has been reported. Firm conclusions based on these early observations await further robust studies.

**Neonatal Toxicity**

Both withdrawal symptoms and direct pharmacological toxic effects can occur after prenatal exposure to any antidepressant. Simon et al. recently reported lower APGAR scores after third trimester SSRI exposure. Anticholinergic stimulation causing bladder distension and gastrointestinal stasis in newborns has been described. Serotonin over-stimulation (myoclonus, restlessness, tremor, shivering, hyper-reflexia, incoordination, rigidity) with fluoxetine, paroxetine, and sertraline has also been reported.

The risk of withdrawal reactions may be greater with short half-life drugs such as paroxetine and venlafaxine when compared with fluoxetine. The half-lives of paroxetine and venlafaxine when compared with fluoxetine. The half-lives of paroxetine and sertraline are similar at 24 hours but the largely inactive metabolite of sertraline, desmethylsertraline, is eliminated slowly, which prevents occurrence of frequent withdrawal reactions. It has been suggested that a dose taper before delivery will minimize the fetal drug load at birth. However, predicting labor is rarely accurate; therefore, this decision requires clinical judgment based on a risk-benefit analysis.

**Behavioral Teratogenicity**

Antepartum exposure to agents that affect the central nervous system can impact the neurology and behavior of the infant in the postpartum period. Oberlander et al. examined pain sensitivity in SSRI-exposed neonates relative to controls and found attenuated acute pain response in the SSRI-exposed group that persisted at 2 months of age. Increased tremulousness, increased sleep times and REM sleep in newborns exposed to SSRIs relative to unexposed newborns has been recently reported. The long-term significance of these findings remains to be established. In a 7-year follow-up study, Nulman et al. reported that global IQ, verbal comprehension, expressive language development, temperament and general behavior were similar in children exposed at any time in pregnancy to tricyclics or fluoxetine compared with controls. Similar studies on newer drugs are not available.

**Impact of Postpartum Illness on Infant Development**

A large body of literature suggests that a mother’s attitude and behavior toward her infant significantly affects mother-infant bonding and infant well-being and development. Depression not only hurts the mother, but also affects her family. Postpartum depression can affect a mother’s ability to parent. As a result, she may feel guilty and lose confidence in herself as a mother, which can worsen the depression. Mothers may harm their child during period of psychosis. Postpartum depression can affect the infant by causing delays in language development, problems with emotional bonding to others, behavioral problems, sleep problems, and distress. It helps if the father or another caregiver can assist in meeting the needs of the baby while mother is depressed. All children deserve the chance to have a healthy mother. All mothers deserve the chance to enjoy their life and their children. Do not suffer alone.

**Breastfeeding and Psychotropic Medications**

Women who plan to breastfeed must be informed that all psychotropic medications, including antidepressants, are secreted into breast milk. Concentrations in breast milk vary widely. Data on the use of tricyclic antidepressants, fluoxetine, sertraline, and paroxetine during breastfeeding are encouraging, and serum antidepressant levels in the nursing infant are either low or undetectable. Reports of toxicity in nursing infants are rare, although the long-term effects of exposure to trace amounts of medication are not known. Avoid breastfeeding in women treated with lithium. Avoid breastfeeding in premature infants or in those with hepatic insufficiency who may have difficulty metabolizing medications present in breast milk.¹³

**PREVENTION**

In most cases postpartum depression is preventable; early identification can lead to early treatment. A major part of prevention is being informed about the risk factors and education about identifying postpartum depression. Also, proper exercise, nutrition including proper hydration and
vitamin supplements, plays a role in preventing postpartum, and general, depression.

The high risk group of women who can develop postpartum psychosis is not clearly delineated but certain subgroups can be identified particularly those with a history of mood disorder, prior episode of psychosis. In such cases prophylactic interventions may be instituted near or at the time of delivery to decrease the risk of postpartum illness.14

**SUMMARY**

The puerperium is undoubtedly a time when a woman has an increased risk of developing a psychiatric disorder. Table 1 describes in short the various disorders and the treatment modalities. Childbirth is not a straightforward single life event and may best be considered as a cascade of life events; some, such as the birth itself, are initiated by physiological changes whilst others, such as the new social role of the mother, are determined by sociocultural variables. Much road has to be covered in our country to understand these disorders and to formulate long-term preventive goals.

**REFERENCES**

INTRODUCTION

Postpartum exercises and physiotherapy should be one of top priorities, because of the current trend towards briefer hospital stay and health awareness amongst the new mothers and her family. Also, it minimizes complications related to blood clotting. Its advantages have been tabulated in Table 1. Much innovative thinking is urgently required, because there will have to be substantial changes in the provision of immediate postnatal care and rehabilitation in hospital and its continuation in the community.

An average pregnant woman gains 10–12 kg during pregnancy. 5–6 kg weight is usually lost within a month of having baby. But this 3 or 4 kg can be hard to get rid of. With a little patience and consistent exercise program, one can get back to shape after delivery. However, before you do any exercise you should consult your doctor.

Simple exercises that one can do in the first few hours and week after birth are light exercises like walking and modified push-ups stretching especially if delivery is vaginal normal delivery.

Kegel’s exercises can also be started early since they involve small contractions of the muscle of the vaginal wall. Kegel’s exercise can help strengthen weak pelvis muscles, which could cause bladder control problems. Another easy one is walking! Short slow walks will help. A mother’s body gets ready for more vigorous exercises after the first few weeks. Walking at an easy pace is encouraged as it promotes healing and helps in preventing the complications related to blood clotting.

ASSESSMENT

Ideally, at a mutual convenient time within the first 24 hours, the obstetric physiotherapist should assess each new mother to determine her priority needs. Immediate advice and initial exercise instruction is best given individually, and specific therapies, where necessary, should be commenced as soon as possible.

However, after this it is more cost-efficient, more effective and much more pleasurable for the women to participate in postnatal classes. Most new mothers enjoy being in a group and benefit from the opportunity to exchange experiences, moan and laugh, discuss problems and work through ways of solving them together.

There is a wealth of information and advice, over and above simple exercise instruction, which is particularly important for those women who did not attend antenatal classes. The postnatal class can be taken in the parent craft from, if it is nearby, or the ward day-room. Most women are happy to participate, but only if their babies can come too. This should definitely be encouraged because it enables valuable teaching to be presented regarding the new activities, especially baby feeding and nappy changing, which if carried out incorrectly can lead to neck and back ache. Where women are cared for in single rooms and no common room exists, obstetric physiotherapists will be very restricted in what they can offer at this special time.

Table 1: Advantages of postnatal exercises

- It raises your metabolism
- It helps you shed those extra kilos
- It provides energy to deal with your chaotic life
- It gives you a little time for yourself
- It helps relieve stress and body tension.
Most women develop a gap in their abdominal muscles during pregnancy and labor. It takes 4-8 weeks after birth for this gap to close. Exercising before the gap closes can risk injury to muscles. If the diastases are less than two fingers in width, abdominal exercises like crunches or situps can be started. If the gap is greater, rotation and side flexion exercises should be delayed until the size of the gap has been reduced. Such movements may increase the gapping because of shearing forces. Static and gentle dynamic inner-range exercise may be performed with crossed hands.

One may like to perform her pelvic floor exercises at the one of labor or when you exhale lift your head and your shoulder off the floor and slide your right hand up your thigh towards your knee. This will make your abdomen muscles tighten and you should be able to feel the gap where muscles have separated. If the gap is more than 3-4 fingers you can gently begin to strengthen your abdominal muscles with pelvic tilts and leg slides.

The primary aims are to shorten stretched muscle fibers, close any diastases and strengthen weakened muscles. The first step in abdominal muscle re-education should be the initiation of a simple contraction, for example, drawing in the anterior abdominal wall in crook lying. It is most efficient when it is combined with expiration. However, many women cannot do this easily. The physiotherapist may find it helpful to suggest that women "breathe in breathe out, draw the tummy in-and then relax". A common fault is attempting to combine abdominal wall retraction with inspiration and breath holding. This has the effect of raising the rib cage with its abdominal wall attachments, thereby taking up the slack, possibly without any muscle contraction. For some women it will be much easier to initiate an abdominal muscle contraction side-lying. Because the abdomen protrudes and sags sideways the muscle fibers are in their outer to middle range—their pre-delivery state and this seems to make it easier to active a contraction. A similar situation exists in sitting women who can both see and feel their abdominal movement.

• One can perform these exercises lying down, sitting, standing or on your hands and knees
• Keep the lower back flat
• Breathe out, and draw your belly button back towards your spine. The lower back should not flex or move.
• Hold this position and breathe lightly. Count to 10.
• Relax, and repeat up to 10 times per set.
• One should do 10 sets, as many times per day as she can.
• One may like to perform her pelvic floor exercises at the same time.

Pelvic tilting can also be taught crook or side lying, again, it can be done slowly, holding the abdominal wall in while the mother counts to four, or it can be done quickly (tilt, relax,
Postpartum Exercises

Fig. 1

Fig. 2

Fig. 3

Fig. 4
tilt, relax). This second technique is often very helpful for the woman who has after pains or backache. The obstetric physiotherapist must be vigilant because it is possible to tilt the pelvis in crook lying without contracting the abdominal muscles; rhythmic gluteal contraction will help ease the pain from hemorrhoids.

**THE EARLY POSTNATAL CLASS**

All too often postnatal exercise are only taught to women who are lying down, this may well be one of the reasons why many of them fail to continue exercising, once they return home. If a woman does not realize that it is possible to strengthen her abdominal and pelvic floor muscles while she is standing or sitting, early exercises will not be done simply because she may never have time to lie down!

**Simple Postnatal Exercises**

**Walking (Figs 5A and B)**

After the 1st week, a slow to moderate walk of 30 minutes three times a week is fine. As one regains strength, you can increase the length or number of walks. If a mother had a cesarean section, then she should wait for 6–8 weeks before starting the exercises.

Walking at an easy pace is encouraged as it promotes healing and helps in preventing the complications related to blood clotting. It is important to remember that your joints and ligaments will remain loose for next 3–5 months, so vigorous exercises are better carried out under supervision of experts. Do not overdo exercises as your body needs time to heal and you need time to adjust to your new role as a mother.

**Sitting (Figs 6A and B)**

The early hospital class can begin with the women sitting comfortably and well supported on chairs which have been placed in a circle, pillows should be used where necessary for sore perineum and to support back. Women must realize that one of their first postnatal exercises is how they sit when feeding their babies. Once everyone is settled, attention should be drawn to the main areas of muscle weakness (abdomen and pelvic floor) and the problems that can follow misuse of their backs. Multiparous are often important sources of advice, and their previous exercise, can be very useful. The obstetric physiotherapist will find it helpful to have some simple, large diagrams that illustrate the pelvic floor and possible episiotomy sites, as well as the abdominal muscles and the diastases recite abdominals. The Birth Atlas can be used to demonstrate the extent to which their muscles have had to stretch. Women are fascinated by the changes experienced by their bodies during pregnancy and labor, and this realization is often the trigger that stimulates them to continue exercising in order to repair the weaknesses caused by child birth.

Back care advice for feeding, nappy changing, baby bathing, lifting and carrying should all be discussed. Correct heights for cots and pram or buggy handle should be mentioned. Crying babies can be usefully used to explain the value of slings and how they should be worn, with the baby high on the mother’s chest. The women should know that
simple abdominal retraction and pelvic floor work can be done while feeding (once they feel confident that both their babies and themselves are doing this correctly). Other easy exercises which may be done in sitting are side flexion and rotation (with the abdominal muscles well drawn in), elbow and head circling and foot exercises.

**Standing (Figs 7A and B)**

Similar movements can be carried out while standing: “hip hitching” and gentle trunk forward flexion for its relaxing effect are also useful exercises for the women who just cannot find the time or energy during the first few weeks to exercise lying down. While they are standing the women’s attention should be drawn to their posture, which in many cases will still reflect its adaption to pregnancy or to any postpartum pain they are experiencing. The dramatic differences between the measurements of the abdominal girth when women sags compared to that when “standing tall” (5–12 cm) is wonderfully motivating! Women spend a large part of their day standing if all they remember from this early postnatal class is the fact that post office and bank queues are ideal.
places to practice pelvic floor exercises, they will have learnt a valuable lesson!

**Lying (Figs 8A to C)**

Pillows and wedges should be available for the class to learn stronger abdominal work; mats (if there is no carpet) or rolls of disposable couch covering paper (if there is) will be necessary too. Every woman should be shown how to feel if her recti abdominals muscles have separated, and should understand that strong side flexions and trunk rotations, while lying, should be omitted until the anterior abdominal wall is strong enough to allow these movements without shearing.

In this class pelvic tilting can progress to include head raising and then head and shoulders rising. Prior to any postnatal abdominal exercise it is important to remind the mother to draw in the abdominal wall before the movement commences. If the abdomen bulges or ridges anteriorly it indicates extreme weakness of the recti abdominals muscles, and in such women head-raising should be delayed for at least another 24 hours. Where there is a diastasis of more than two finger-widths it has been suggested that crossed hands may be used to approximate and support the diverging recti muscles, although in fat women it may be difficult to find them! Alternate single leg sliding from crook lying with the abdominal wall retracted and head raised, is another excellent technique for strengthening the recti abdominals muscles if it is properly supervised and ridging does not occur.

Practically, every new mother will be having at least one bath each day, so the concept of exercising while bathing should be introduced. Pelvic tilting, pelvic floor contractions, head and shoulder raising and alternative single leg sliding, with the head raised and the chin tucked on to the chest, while holding the sides of the bath, are all good postnatal “aqua exercises”.

This early class should always be completed by a short relaxation session. Women need to be shown how to use pillows to enable them to lie prone comfortably again. Following a cesarean section, mothers can enjoy lying on their backs with a wedge under their knees. Simple relaxation suggestions linked with deep, calm, slow breathing will often result in one or two women falling asleep—this usefully demonstrates their intense fatigue and the importance of occasional catnaps once they return home.
SUMMARY

- By organizing the class in this manner the obstetric physiotherapist can give women valuable information and advice which can really lead to their full recovery and long-term body awareness, how much are useful and realistic than teaching three.
- Pelvic tilts are performed lying on your back, knees bent, feet flat. Lift your lower back and buttocks slightly off the floor, pushing your pelvis to the floor. Hold for 5 seconds and repeat for five reps. Kegel’s are performed by simply tightening your pelvic floor muscles. Pretend as if you are trying to stop a stream of urine. Do 10–12 Kegel’s every time you feed the baby.
- Try exercising in three 10-minute intervals throughout the day, in order to pace yourself.

- Choose exercises you enjoy.
- Try yoga. It is incredible for muscle flexibility and tone.
- Wear a sports bra over your nursing bra for added support and comfort.
- Eat right. Stay away from caffeine and sugar—they are quick energy-boosters that can leave you feeling empty or moody after they wear off.
- Some medical practitioners recommend waiting 6 weeks to exercise—until after your first postpartum check up.
- Be careful with high-impact leg and back exercises. Your joints and ligaments became relaxed during pregnancy, in order to carry and deliver your bundle. It will take your pelvis, back and legs time to realign and get back to normal.
- Make sure your baby is properly secured and dangerous items are out of harm’s reach before you start to exercise.
INTRODUCTION
Postpartum collapse is an acute emergency which we might face many times in our obstetric career. This dramatic event involves the brain, heart or lungs and may ultimately result in death.\(^1\) The exact incidence is difficult to quote.

Postpartum collapse is a consequence of several clinical conditions related to pregnancy and labor. The different pathologies leading to circulatory collapse are often unexpected and mostly not well understood. Moreover, this complex disorder is characterized by its abrupt onset and unfortunately often ends tragically. However, the major pathologies observed in the complex disorder are the trios of hypotension, hypoxia and disseminated intravascular coagulation (DIC). Immediate institution of resuscitative measures is recommended though may not be effective in all the cases. This means that unless the underlying pathology is diagnosed and the management is specific, only resuscitative measures may not improve the outcome. Clinicians’ experience of managing such rare pathologies is also limited. Because of all these reasons, this complex disorder adds to the significant proportion of maternal deaths. Fetal mortality is also high. Current research has provided more knowledge for the understanding of these clinical problems. These are expected to improve our diagnosis and management. No doubt that the involvement of multidisciplinary experts specially the obstetrician, anesthetist, intensivist and the hematologist is the key (to success) to save the life of the woman.

The causes of postpartum collapse can be classified into nonserious causes and serious causes and also on etiological basis (Table 1).

Nonserious Causes
Hyperventilation, hypoglycemia and vasovagal attacks are the nonserious causes of postpartum collapse. These are self-limiting and maternal observations will rapidly return to normal with simple measures, such as reassurance and changing maternal posture.

Serious Causes
- Massive postpartum hemorrhage (PPH)
  - Atonic
  - Traumatic
- Acute puerperal uterine inversion
- Eclampsia
- Embolism
  - Amniotic fluid embolism
  - Pulmonary embolism (PE)
  - Air embolism

  - Adverse drug reaction.
- Proper intrapartum and postpartum monitoring of normal and instrumental deliveries
- Meticulous fourth stage monitoring
- Preoperative and postoperative care in patient undergoing cesarean deliveries.

**Advance Preparation of Health Care Providers**

It is always better to anticipate complications in high-risk patients and plan the line of management in advance; hence, it is important that health care providers should be prepared in advance to deal with emergency situations.

- Multiple factors will have to be considered during such a dramatic event, higher awareness of maternal risk factors together with active surveillance to identify causes of maternal compromise leading to early intervention and proper communication can minimize maternal morbidity and mortality.
- Meticulous planning for management during pregnancy, labor and puerperium will help to prepare and hopefully prevent poor outcome. This can be achieved by involving multidisciplinary team and clinical consultation with anesthetist and physician while assessing high-risk antenatal patients with coexisting medical conditions.
- Anticipation of any complication antenatally and postnatally.

As pregnancy has lot of physiological changes and patient is already in compensated state, so being vigilant and identifying changes in vitals of patient like pulse, respiration and BP helps in timely intervention.

- To inform seniors and to do documentation
- It is a team work of intensivist, gynecologist, physician and surgeon depending upon the cause of postpartum collapse.

**Training of Health Care Providers**

Resuscitation of newly delivered mother can be challenging, if health care provider is not prepared. Nowadays obstetrician and midwives are expected to be able to provide emergency critical care when required. To overcome these problems, obstetricians and the health care providers should practice emergency skills and drill sessions, including management of eclampsia, massive hemorrhages and cardiopulmonary resuscitation (CPR) by practicing on manikins and simulators and attending various courses of management of critically ill patients.

**Immediate Action to be taken by Clinician While Treating Postpartum Collapse**

- Ensure safe environment for patient and call for resuscitation team
- Obtain history from patient or companion
- To inform seniors and to do documentation
- Obtain consent from the patient or relatives
Resuscitation

As per advance life support group (ALSG), structured approach in the form of A, B, C, D and E.

A: Airway

Clearing airway of secretions or vomiting. Maintain airway by inserting oropharyngeal or nasopharyngeal airway. Whenever required experienced anesthetist should do endotracheal intubation as during pregnancy, there is laryngeal edema and increased risk of regurgitation and aspiration.

B: Breathing

Breathing is assessed by looking, listening and feeling, if no spontaneous respiration than mouth to face mask or ventilation by face mask and ambubag, if it does not resumes then tracheal intubation, if respiration assumes give left lateral position.

High flow supplementary oxygen at flow rate of 12 to 15 L/min is mandatory.

C: Circulation

Circulation is assessed by recording carotid pulse, if carotid pulse is not palpable than chest compression at the rate of 15 compression to two breaths is given until signs of circulation are established or defibrillation is advised. In hemorrhagic shock, two large caliber intravenous (IV) lines should be established, blood is sent for blood group and cross-matching along with rest of the investigation. Hypovolemia is corrected by warmed crystalloids, synthetic colloids and red cells followed by blood components.

D: Disability

Level of consciousness and papillary function reflects the neurological status and cerebral tissue perfusion. The Glasgow Coma Scale is used to assess neurological status. Score of 8 or less requires immediate intubation.

E: Exposure

Adequate exposure of patient to avoid missing of vital information to make definitive diagnosis including vaginal examination to exclude pathology is important. Hypothermia should be prevented during the exposure.

Definitive Care

Once the cause of postpartum collapse has been established, input from the relevant specialist is provided without delay and admission to intensive care unit is required for most of the patients.

Identify cause and following appropriate protocol. After identifying the causes, appropriate protocol should be implemented according to the cause.

After A, B, C, D and E

- Monitor—temperature, pulse and respiration (TPR)/BP/O./arterial blood gas (ABG)/I/O chart.
- Position—left lateral position, head low.
- Infusion—25% glucose 50 mL (IV), IV 500 mL Ringer’s lactate (RL)/blood/fresh frozen plasma (FFP) as required.
- Ventilation—endotracheal intubation/mechanical ventilation.
- For cardiac support—dopamine/dobutamine drip if required.
- If PPH—Follow guidelines for PPH-medical and surgical management
- If hemoperitoneum—exploration
- If eclampsia—follow guidelines for eclampsia
- If acute pulmonary edema, cardiac failure, embolism, septic shock—follow appropriate protocol
- If cardiac arrest—follow CPR protocol.

AMNIOTIC FLUID EMBOLISM

Pathogenesis

Disruption of the physiological barrier of the chorioamniotic membranes results in entry of amniotic fluid in the maternal systemic circulation. Steiner and Luschbaugh (1941) first observed the pathology. Subsequently several other workers, Adamsons et al. (1971), Stolte et al. (1967) observed that mere presence of amniotic fluid in systemic circulation is not pathognomonic. Fetal squames and trophoblasts are normally present in maternal circulation. Other workers (Clark et al. 1995) have suggested that individual human body response to amniotic fluid embolism is that of anaphylaxis. The different obstetric conditions that lead to amniotic fluid embolism are: tumultuous labor, high parity, uterine rupture, meconium stained liquor, cesarean delivery, placental abruption and even suction curettage. However, American College of Obstetricians and Gynecologists have ruled out any association between oxytocin use and amniotic fluid embolism. The pathophysiological changes of amniotic fluid embolism lead to the main issues, e.g. systemic hypotension, hypoxia and consumptive coagulopathy. Breach in the chorioamniotic membranes, placental separation—access of amniotic fluid in the maternal systemic circulation through the disrupted uterine vessels is the triggering factor. This leads to the onset of anaphylactic like reaction depending upon the individual human body response. There is activation of the complement pathway C5a. Chemical mediators that are released include prostaglandins, chemokines, cytokines, endothelin-1 and histamines. There is leukocyte migration and aggregation within the small vessels of the lung. Inflammatory mediators are released. There is transudation of intravascular fluid into the intra-alveolar and interstitial spaces. There is antithrombin effect and also thromboplastin effect of amniotic fluid. The coagulation system is activated, so also the fibrinolytic system. This is due to the effect of platelet
aggregation and release of plasminogen activator. Besides these biochemical changes, there is mechanical obstruction of pulmonary vessels causing pulmonary hypertension. The ultimate effects of all these pathological process are: severe hypoxia, left ventricular dysfunction or failure, imbalance of ventilation—perfusion, cardiopulmonary failure leading to shock. The majority of these patients develop hemorrhage due to coagulopathy.

Clinical Presentation and Diagnosis

Patient develops dyspnea, cough, pink frothy sputum and cyanosis. Very soon this phase passes into apnea, loss of consciousness and circulatory collapse. A few patients develop convulsions and majority develop coagulopathy.

Diagnosis is generally made by analyzing the clinical characteristics. Detection of squamous cells or fat, trophoblasts in the blood obtained from the central circulation via central venous pressure (CVP) measuring catheter, may be suggestive when the patient suffers with the clinical manifestation of amniotic fluid embolism. Hemodynamic measurements are obtained through the right heart catheterization. Immediately after the embolism, there is elevated pulmonary capillary wedge pressure (PCWP) and CVP. Electrocardiogram shows right axis deviation and there is evidence of acute right ventricular dysfunction. Cardiac output is decreased resulting in left ventricular failure.

Management

Principles of management are to initiate effective resuscitative measures immediately. Patient’s airway must be maintained to provide effective ventilation and oxygenation. Monitoring of the hemodynamic parameters is essential. Prevention of left ventricular dysfunction or failure and to start digitalization if needed. Infusion of dopamine L dobutamine may be needed to improve myocardial contractility and hemodynamic normalization. Maintenance of CVP and PCWP with crystalloid is continued. Prevention and or management of DIC is another important area. Deranged coagulation parameters should be treated by FFP, cryoprecipitate or fibrinogen. Heparin may also be needed in a few cases. Metabolic and electrolyte abnormalities should be corrected. Broad spectrum antibiotic coverage is needed to prevent any infection. All these supportive care measures are continued with monitoring till the cardiorespiratory functions are stabilized. Prognosis: unfortunately in spite of all the care, maternal mortality from amniotic fluid embolism is about 60–90%. The woman that survive often suffer from some neurological impairment.

Uterine artery embolization is a useful noninvasive technique which may be effective. Plasmapheresis and hemofiltration have been advocated and shown to be successful in arresting the progress of the disease, probably by clearing the plasma of cytokines.

PULMONARY THROMBOEMBOLISM

Overall incidence of pulmonary venous thromboembolism in pregnancy is about 1 in 2,500 pregnancies. Majority occur (75%) in immediate postpartum period. It is one of the significant causes of maternal deaths in many countries.

Pathogenesis

The risk of thromboembolism is increased in pregnancy or puerperium due to several physiological changes (Table 2). Increase in the level of coagulation factors (factors I, VII, VIII, IX, X) progressive rise in venous pressure in the leg veins, trauma of delivery either vaginal or cesarean section, and associated infection increase the risk of venous thrombosis and thromboembolism. There is decline in the level of proteins during pregnancy. Hypercoagulable state of blood and the vascular endothelial injury are the two main initiating factors. In some women, inherited deficiency of some regulatory proteins (thrombophilias) may be associated. Other high risk factors are elderly age of the woman (≥35 years) obesity, hypertension, high parity and operative delivery.

Clinical Presentation

In some women, clinical evidence of deep vein thrombosis in leg veins precedes PE. But in others, they remain asymptomatic until embolization occurs. The most common presenting symptoms are: dyspnea (80%), chest pain (50%), cough, syncope and hemoptysis. Clinical examination may reveal tachycardia and tachypnea, friction rub, cyanosis and circulatory collapse. ECG may reveal T-wave inversion and right axis deviation. Chest X-ray shows less vascular area of the lung field supplied by the obstructed artery. One should be careful that is normal blood gas report does not rule out PE.

Diagnosis

Diagnosis of PE is difficult. A high index of suspicion combined with the tests is helpful.

Ventilation perfusion lung scan: Segmental perfusion defects in association with normal ventilation and normal chest X-ray are seen. When ventilation-perfusion scan is equivocal, pulmonary angiography is performed. V/Q scan can detect large perfusion detects but a normal V/Q scan does not rule out PE.

Pulmonary angiography is done in selected cases only to detect the site and size of block. It has several complications like cardiac arrest, arrhythmia, allergic reactions due to the dye or even renal failure.

Spiral computed tomography (spiral CT) is helpful for imaging main pulmonary arteries and also the segmental branches. The four-channel multidetector spiral CT is
Magnetic resonance angiography has got the advantage of high resolution and without any risk of radiation. The sensitivity and specificity of magnetic resonance angiography are similar to that of spiral CT.

Management

Immediate resuscitative measures include maintenance of airway, ventilation and oxygenation. Hemodynamic circulatory status is maintained with isotonic crystalloids. Drug of choice for PE is intravenous heparin. An initial bolus dose of 5,000–10,000 units of heparin IV followed by a continuous infusion of 1,000 units/hour. The dose is adjusted to maintain the partial thromboplastin time at 1.5–2 times the control or the serum heparin concentration at 0.2–0.7 IU/mL. Heparin IV is continued for a minimum of 7–10 days, following which oral anticoagulants (Warfarin) are started. The major complication faced with the use of these drugs is hemorrhage. One should be careful when any surgical procedure is to be done in such a woman.

Thrombolysis is helpful to lyse the pulmonary clots. Risk of recurrence is lower when thrombolytic agents are compared to heparin. Recombinant tissue plasminogen activator is currently being used.

Surgery

Patient having massive PE may be treated with pulmonary embolectomy from the main pulmonary arteries. During pregnancy embolectomy is avoided in preference to vena cava filter. In cases with recurrent PE even with heparin therapy, vena cava filter (umbrella) may be indicated. Ligation of inferior vena cava has been done as an alternative in the management of recurrent PE.

**ACUTE INVERSION OF THE UTERUS**

This is an uncommon condition, the reported incidence is 1 in 2,500 deliveries. It may be complete or incomplete depending upon the descent of fundus through the cervical ring and vaginal introitus. It results in a varying degree of shock mostly of neurogenic origin due to traction of infundibulopelvic ligament. It can also result in PPH.

The most common cause of inversion is fundal placentation with excessive cord traction in third stage of labor when uterus is not well contracted. Uterine over distension and prolonged labor or morbid adherent placenta are some of the predisposing factors.

**Clinical Presentation, Diagnosis and Management**

Clinical presentation includes pain in the lower abdomen, vaginal bleeding and the sensation of vaginal fullness. Clinical features of shock are evident and often there is out of proportion to the amount of blood loss. Cupping of the fundus is felt on abdominal examination. On vaginal examination, the inverted uterus is felt as a soft purple mass. Diagnosis is made on clinical examination keeping in mind the differential diagnosis. A large uterine or cervical polyp occupying the vagina often needs to be excluded. Real time ultrasound scan may be helpful. Management needs immediate resuscitation to overcome the shock which is often expected to be the gold standard to replace the pulmonary angiography.³⁵

### Table 2: Acquired risk factors of thrombosis during pregnancy

</table>

Abbreviations: DIC, disseminated intravascular coagulation; GIT, gastrointestinal tract; BMI, body mass index; DVT, deep vein thrombosis
neurogenic. Volume replacement with crystalloids or blood is essential specially when it is accompanied by hemorrhage. Actual management involves immediate manual reposition of the uterus. Principle of manual reposition is to push the part of uterus first that came out last. Halothane anesthesia is recommended as it relaxes the cervical ring and helps in smooth reposition. Hydrostatic correction (O’Sullivan, 1945) is also done as an alternative procedure. In cases where the placenta is still attached, manual removal of placenta is done only after the reposition of the uterus. Oxytocics (oxytocin, ergometrine or PGF$_2$α are to be used following the correction to prevent reinversion of the uterus.

### REGIONAL ANESTHESIA/DRUG TOXICITY OR SELF POISONING (SUICIDE)

Toxicity with regional anesthesia is relatively less common. However, pregnant women are more susceptible to the toxic effects, compared to the nonpregnant ones. This is due to the effects of increased vascularity of the epidural and subarachnoid space. The patients on magnesium therapy are at risk and those having postnatal depression or alcohol and drug abuse history.

**Pathophysiology**

It results from inadvertent intravascular injection of the anesthetic agents. Any local anesthetic drug specially, if a long-acting (bupivacaine, etidocaine) one given in high doses, results in more systemic toxicity. High spinal blockage due to excessive dose results in hypotension, apnea and even cardiac arrest or myocardial depression.

**Diagnosis**

Common clinical features of systemic toxicity are metallic taste in the mouth, ringing in the ears, confusion or dyspnea. Sympathetic blockage results in hypotension, ptosis, miosis. Apnea may develop due to respiratory muscles paralysis. Cardiac arrest may develop due to hypoxia or due to the direct toxic effects of the drug. Convulsions though rare may be due to the effects of hypoxia. Magnesium toxicity is recognized by respiratory arrest and treated by administration of calcium gluconate.

**Management**

Resuscitative measures including maintenance of airway, ventilation and oxygenation has to be initiated immediately. To control convulsions, diazepam IV is to be administered. Resuscitative measures are to be continued till the effects of local anesthetic drugs have dissipated. Prognosis is usually satisfactory provided there is early recognition of complications and the effects of hypoxia and metabolic derangements do not develop.

### MYOCARDIAL INFARCTION

Acute myocardial infarction is not an uncommon complication. This is more common during the third trimester or in the immediate postpartum period. The maternal mortality is as high as 30–50%.

The high-risk factors for acute myocardial infarction are hypertension, pre-existing heart disease, hyperlipidemia, diabetes, obesity and elderly women.

**Clinical Presentation**

Signs and symptoms of this medical disorder are similar to that of nonpregnant state. The important features are substernal pain, nausea, vomiting, dyspnea. There may be radiation of pain into the neck and the left arm. When complications set up there may be arrhythmia pulmonary edema, or features of congestive cardiac failure or cardiogenic shock.

**Diagnosis**

It is similar to that of a nonpregnant condition. ECG changes and alternations in different cardiac enzyme levels are suggestive. Significant ECG changes in acute myocardial infarction include ST segment elevation, Q waves in leads II, III and AVF or poor R wave progression in the precordial leads. Cardiac enzyme estimation shows an elevation of creatinine phosphokinase, SGPT, SGOT and lactic acid dehydrogenase.

**Complications**

Several complications may develop in some of the cases. Cardiac arrhythmia, ectopic atrial or ventricular beats, ventricular tachycardia, fibrillation or heart block may develop.

In severe cases with large infarctions, congestive cardiac failure or cardiogenic shock may develop. Death is not uncommon from massive myocardiac infarction in the immediate postpartum period.

**Management**

Resuscitative measures for a woman with acute myocardial infarction in labor or in immediate postpartum period are the maintenance of patient’s airway, ventilation and oxygenation. Dopamine or dobutamine may be used when vasopressor drugs are needed. Arrhythmias, like ventricular fibrillation, tachycardia, may be treated with electric shock therapy. Heart block is treated with atropine or by a pacemaker. For definitive management, the patient needs to be transferred to a coronary care unit.
HEMORRHAGIC SHOCK

Pathogenesis

Massive PPH is still a major cause of maternal death and morbidity. Massive hemorrhage occurs in approximately 1,000 deliveries. Although PPH is classically defined as loss of 500 mL blood, blood loss exceeding 1,000 mL results in hemodynamic instability. Massive hemorrhage is defined as a blood loss of about 50% of blood volume in 3 hours or more than 150 mL/min blood loss. Hemorrhagic shock may be mild when 15–25% of blood volume is lost, whereas moderate shock is when 25–35% of blood volume is lost.

Atonicity of uterus is the most important cause of PPH. Over distended uterus due to twin, big baby or polyhydraminos, retained placental bits or membranes, prolonged labor, labor augmented by oxytocin, multiparity, uterus malformation are some of the predictable factors for atonic uterine bleeding in the postpartum period. Laceration and hematomas occur commonly following difficult, manipulative and operative deliveries. DIC often is the end result of various conditions as preeclampsia, intrauterine fetal demise (IUFN), abrupton placenta, amniotic fluid embolism, septicemia and hypovolemia.

Clinical Features, Diagnosis and Treatment

Tachycardia, hypotension, pallor, cold clammy extremities, low urinary output are the hallmarks of hemorrhagic/hypovolemic shock. Central nervous pressure and pulmonary wedge pressure monitoring helps in assessment of intravascular volume and helps in differentiating with non hemorrhagic shock. Evaluation of a patient with hemorrhagic shock includes estimation of hemoglobin, platelet count, measurement of prothrombin time and activated partial thromboplastin time, fibrinogen and fibrin degradation products.

Management

- Significant blood loss from any cause needs standard maternal resuscitation measures
- Appropriate intravenous access is critical
- One or two large bore IV catheters are introduced
- Estimation of blood loss and volume replacement begins with warm crystalloid solutions. Colloids and blood component replacement is needed according to the individual patients need and blood loss.

Drugs: Uterotonics are the mainstay in atonic PPH. Oxytocin, methylergometrine, PGF2α, and misoprostol are the different drugs used. In recent reviews, the promise of misoprostol is highlighting because of its low cost, ease of administration (per rectal) quick onset of action, mild side effect and lack of contraindications. 1,000 µg of misoprostol rectally is highly effective in controlling PPH due to atonic uterus.

Other Procedures

- Uterine massage: Bimanual uterine massage can effectively control PPH due to atonicity.
- Re-emergence of uterine packing: Tight intrauterine gauge pack, Foley’s catheter with 30 mL balloon or a Sengstaken-Blakemore tube have all been used for tamponade inside the uterine cavity of desperate situation. They need to be removed after 12–24 hours and found highly effective.
- Surgical: Compression sutures, B Lynch suture, has gained most popularity.
  - Stepwise devascularization of uterine, utero-ovarian and anterior division of internal iliac arteries is helpful in many cases where uterus has to be preserved.
  - Hysterectomy: Supracervical hysterectomy may be the final definitive management in an unstable patient with torrential bleeding not controlled with initial measures.

Management of Massive Hemorrhage

Management of massive hemorrhage has been summarized in Table 3.

Fluid Management

A 2006 guideline from the British Committee for Standards in Haematology summarizes the main therapeutic goals of management of massive blood loss is to maintain:

- Hemoglobin more than 8 g/dL
- Platelet count more than $75 \times 10^9$/L
- Prothrombin less than 1.5 x mean control
- Activated prothrombin times less than 1.5 x mean control
- Fibrinogen more than 1.0 g/L

By consensus, total volume of 3.5 L of clear fluids (up to 2 L of warmed Hartmann’s solution as rapidly as possible, followed by up to a further 1.5 L of warmed colloid if blood is still not available) comprises the maximum that should be infused while awaiting compatible blood. There is controversy as to the most appropriate fluids for volume resuscitation. The nature of fluid infused is of less importance than rapid administration and warming of the infusion. The woman needs to be kept warm using appropriate measures. This consensus advice must be viewed with a certain degree of caution, because there is evidence that infusion of such volumes promotes or exacerbates dilutional coagulopathy.

Medical Management

Medical management has been described in Table 3 and also in Chapter 39 in detail.
Mechanical Methods

Balloon Tamponade

In recent years, tamponade using various types of hydrostatic balloon catheters has superseded uterine packing for control of atonic PPH. Case series have used a Foley catheter, Bakri balloon, Sengstaken-Blakemore esophageal catheter and a condom catheter. The urological Rusch balloon has been described as preferable by virtue of large capacity, ease of use and low cost. A group from Sheffield has provided a detailed protocol for uterine tamponade using the Rusch balloon. The Scottish Confidential Audit of Severe Maternal Morbidity identified 64 cases where balloon tamponade was used for the management of major PPH; hysterectomy was averted in 50 (78%) women. This success rate is of the same order as that reported in other case series.

Some of the reports of balloon tamponade describe the intervention as the tamponade test. A positive test (control of PPH following inflation of the balloon) indicates that laparotomy is not required, whereas a negative test (continued PPH following inflation of the balloon) is an indication to proceed to laparotomy.

The concept of balloon tamponade as a “test”, serves to affirm its place as first-line “surgical” management. There is no clear evidence how long the balloon tamponade should be left in place. In most instances, 4–6 hours of tamponade should be adequate to achieve hemostasis; ideally, removal should take place during daytime hours and in the presence of appropriate senior staff if further intervention is necessary. Before its complete removal, however, the balloon can be deflated but left in place to ensure that bleeding does not recur.
Surgical Techniques

B-Lynch Suture

The B-Lynch suture, first described in print in 1997, has been used worldwide. More than 2,000 cases have been reported to the website http://www.cbl.uk.com with less than 10 requiring hysterectomy. Analysis of failures suggest that, in most cases, the operation was conducted late (often as late as 6 hours) when problems in clotting would be expected to be present. The sutures provide uterine compression so that hemostasis is maintained for prolonged times. It is, in effect, a continuous form of bimanual compression. The analogy offered by Professor Lynch is that the operation is the same as wearing a belt and braces (suspenders) at the same time in an effort to hold up one’s pants.

The operation requires minimal training, conserves the uterus, is less technically challenging and associated with less blood loss than hysterectomy. Further details are available in the Textbook of Postpartum Hemorrhage which also can be downloaded for free at http://www.sapienspublishing.com/medical-publications.php#1. The importance of this operation is such that many teaching programs make it an integral part of the instruction for cesarean delivery, stating that properly trained surgeons must know both techniques as PPH can occur at any time.

Hysterectomy

The decision to perform hysterectomy to control PPH is difficult. Death is the most likely outcome if one is incorrect in choosing to perform hysterectomy to save a life in the presence of intractable PPH. This is not to say that the surgery is technically simple, because the postpartum uterus does not present the same anatomic landmarks to aid the surgeon, and tissue planes do not always resemble their counterparts in the nonpregnant situation.

Regardless, hysterectomy (total or subtotal and with or without adnexectomy) remains a mainstay of the therapy of PPH, because it is likely that doctors will have had experience with this technique.

Emergency peripartum hysterectomy is an unequivocal marker of severe maternal morbidity and “near miss” mortality.

The indications for hysterectomy include abnormal placentation, persistent uterine atony, uterine trauma after variety of obstetric manipulations, lateral traumatic extension of the lower uterine segment incision into the uterine artery and sepsis. An equipment tray that is specially for PPH has been described.

Internal Iliac Artery Ligation

The importance of this operation cannot be underestimated. In fact, many teaching programs recognize that it is best to practice in the nonemergent situation or at the autopsy table. The physiology of the surgery is quite simple. The excellent collateral circulation of the pelvis protects the uterus from ischemic necrosis, because the hypogastric artery distal to the point of ligation is never truly emptied of blood, and the rich anastomotic network begins to function immediately after ligation. What happens is the virtual elimination of the arterial pulse pressure, associated with reduced mean BP and rate of blood flow in the collateral system. As a result, the trip hammer effect of arterial pulsations is abolished. Bilateral ligation is always more effective than a unilateral procedure and diminishes the chance of returning to the operating room for further surgery. Differentiation between prophylactic and therapeutic ligation is by no means absolute.

Adjunctive Measures

Nonpneumatic Antishock Garment

The comprehensive therapy of a patient with PPH often requires transfer of a desperately ill patient over long distances to a higher level facility. Under the best of circumstances, such transfers may be life threatening. A major advance in providing safe transfer has been the development and implementation of the nonpneumatic antishock garment (NASG). Unlike its predecessor garments, there are no pumps, tubes or gauges to add complexity or malfunction. Using the three way elasticity of neoprene and the tight grip of Velcro fasteners, the garment can apply 30-40 mm Hg of circumferential counter pressure to the lower body from the ankles to the diaphragm. This amount of pressure is effective in shunting blood from the lower extremities and the abdomen (5–1,500 mL) to the vital core organs. Widely tested in Egypt, Africa and Mexico, the garment is now used successfully in many areas of the world to provide additional safety during patient transport.

Aortic Compression

Occasionally during an operating to correct bleeding from PPH, blood loss is so massive and so rapid that death may ensue within a very short time. Such circumstances are not uncommon in the treatment of morbidly adherent placentas. A helpful measure is a temporary occlusion of the abdominal aorta (below the renal arteries) by manual pressure provided by a surgical assistant. This sounds easier than it actually is in real life, because the pressure required is equivalent to the pressure that one would have to make on a bathroom scale to reach the number 41 kg (90 lbs). Such pressure allows the surgeon to work with a much drier field and perhaps achieve better hemostasis and also facilitates clot formation at the traumatized vessels. External aortic compression device has been suggested as a simple and cost-effective approach in the management of PPH, especially in the developing countries.
SEPTIC SHOCK

Although rare in developed world, septicemia is one of the important causes of maternal mortality and morbidity in developing countries. Septic shock is the systemic inflammatory response to infection. It is manifested by hypotension, oliguria, lactic acidosis, perfusion abnormalities, acute respiratory distress and altered mental state. A variety of aerobic and anaerobic organisms are responsible for septic shock. There common organisms are: Escherichia coli, Klebsiella, Proteus mirabilis, Pseudomonas, Staphylococcus aureus and Bacteroides. Factors predisposing to such infection are PROM and chorioamnionitis, IUFD, surgical intervention, urinary tract infection and pyelonephritis, appendicitis and ovarian abscess.

Septic shock occurs when the offending organisms invade the maternal circulation and liberate endotoxins and exotoxins. All these interact with leukocytes and endothelial cells causing liberation of various mediators, such as cytokines, nitric oxide, prostaglandins, leukotrienes and tissue necrotic factor. These are responsible for all the clinical manifestation of septic shock.

The various biochemical and pathological abnormalities observed in septic shock are: (1) diffuse intravascular coagulation, (2) metabolic acidosis, (3) release of super oxide ($O_2^-$) and hydroxyl (OH$^-$) radicals, (4) failure of sodium pump operation, and (5) water and electrolyte imbalance. Organ changes are observed in the kidneys, liver, gastrointestinal tract, lungs and the myocardium also. Ultimately, multiple organ failure develops.

Management of Septic Shock

Investigations include complete hemogram, chest X-ray, septic work-up (including blood culture, vaginal swab), blood gas analysis, hepatic and renal function tests and coagulation profile.

The principles of management include control of infection, circulatory volume maintenance, adjustment of acid-base balance, maintenance of hemodynamic stability, ventilatory support and removal of the source of infection.

- Antibiotics are selected to cover the Gram-negative and Gram-positive aerobic organisms and the anaerobes. High dose parenteral regimen is initially started till the culture report is obtained for the specific organism and its sensitivity.
- Intravenous fluids (crystalloids, colloids, blood transfusion) to be administered and normal serum electrolytes levels are to be maintained. Maintenance of CVP, renal perfusion (urine output) and BP are to be continued.
- Correction, hypoxemia and metabolic acidosis are done simultaneously.
- Inotropic agents in a critically ill patient (dopamine/dobutamine) may be needed to improve myocardial contractility and perfusion pressure.

Corticosteroids are used in selected cases only. Disseminated intravascular coagulation is treated with FFP or whole blood transfusion. Heparin therapy may be considered in some cases.

Elimination of the source of infection should be done at the earliest whenever the patient is hemodynamically stable. Hysterectomy has been recommended in some septic cases.

ECLAMPSIA

Introduction

- Incidence: 2–3 per 100
- Risk factor: Preeclampsia
- Clinical symptoms/signs: Grand mal convulsion, postictal drowsiness, hypertension, hyperreflexia

Protocols for Management (Box 1)

Anticonvulsive Drugs

A key factor in anticonvulsive therapy is adequate administration of anticonvulsive drugs. Convulsions in hospitalized women are most frequently caused by undertreatment. Magnesium sulfate is the drug of choice for preventing and treating convulsions in severe preeclampsia and eclampsia. Administration is outlined in Table 4.

<table>
<thead>
<tr>
<th>Box 1: General management for eclampsia</th>
</tr>
</thead>
<tbody>
<tr>
<td>- Start an IV infusion and infuse IV fluids</td>
</tr>
<tr>
<td>- After the convulsion:</td>
</tr>
<tr>
<td>- Give anticonvulsive drugs</td>
</tr>
<tr>
<td>- Position the women on her left side to reduce risk of aspiration of secretions, vomit and blood</td>
</tr>
<tr>
<td>- Aspirate the mouth and throat as necessary</td>
</tr>
<tr>
<td>- Monitor vital signs (pulse, BP, respiration), reflexes and fetal heart rate hourly.</td>
</tr>
<tr>
<td>- If diastolic BP remains above 110 mm Hg, give antihypertensive drugs. Reduce the diastolic BP to less than 100 mm Hg but not below 90 mm Hg.</td>
</tr>
<tr>
<td>- Catheterize the bladder to monitor urine output and proteinuria.</td>
</tr>
<tr>
<td>- Maintain a strict fluid balance chart (monitor the amount of fluids administered and urine output) to prevent fluid overload.</td>
</tr>
<tr>
<td>- If urine output is less than 30 mL per hour.</td>
</tr>
<tr>
<td>- Withhold magnesium sulfate and infuse IV fluids (normal saline or RL) at 1 L in 8 hours</td>
</tr>
<tr>
<td>- Monitor for the development of pulmonary edema</td>
</tr>
<tr>
<td>- Never leave the woman alone. A convulsion followed by aspiration of vomit may cause death of the women and fetus</td>
</tr>
<tr>
<td>- Auscultate the lung bases hourly for rales indicating pulmonary edema. If rales are heard, withhold fluids and give frusemide 40 mg IV once.</td>
</tr>
<tr>
<td>- Assess clotting status with a bedside clotting test. Failure of a clot to form after 7 minutes or a soft clot that breaks down easily suggests coagulopathy.</td>
</tr>
</tbody>
</table>
If magnesium sulfate is not available, diazepam may be used. Although a single dose of diazepam seldom causes neonatal respiratory depression, long-term continuous IV administration increases the risk of respiratory depression in babies who may already be suffering from the effects of uteroplacental ischemia and preterm birth. The effect may last several days. Administration of diazepam is outlined in Table 5.

**Antihypertensive Drugs**

If the diastolic BP is 110 mm Hg or more, give antihypertensive drugs. The goal is to keep the diastolic pressure between 90 mm Hg and 100 mm Hg to prevent cerebral hemorrhage. Hydralazine is the drug of choice.

- Give hydralazine 5 mg IV slowly every 5 minutes until BP is lowered. Repeat hourly as needed or give hydralazine 12.5 mg intramuscular every 2 hours as needed.

---

**Table 4: Magnesium sulfate schedules for severe preeclampsia and eclampsia**

<table>
<thead>
<tr>
<th>Loading dose</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Give 4 g of 20% magnesium sulfate solution IV over 5 minutes</td>
</tr>
<tr>
<td>• Follow promptly with 10 g of 50% magnesium sulfate solution—give 5 g in each buttock as a deep intramuscular (IM) injection with 1 mL of 2% lignocaine in the same syringe. Ensure aseptic technique when giving magnesium sulfate deep IM injection. Warn the woman that a feeling of warmth will be felt when magnesium sulfate is given.</td>
</tr>
<tr>
<td>• If convulsions recur after 15 minutes, give 2 g of 50% magnesium sulfate solution IV over 5 minutes.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Maintenance dose</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Give 5 g of 50% magnesium sulfate solution with 1 mL of 2% lignocaine in the same syringe by deep IM injection into alternate buttocks every 4 hours. Continue treatment for 24 hours after delivery or the last convolution, whichever occurs last.</td>
</tr>
<tr>
<td>• If 50% solution is not available, give 1 g of 20% magnesium sulfate solution IV every hour by continuous infusion.</td>
</tr>
</tbody>
</table>

**Closely monitor the women for signs of toxicity**

Before repeat administration, ensure that:

- Respiratory rate is at least 16 per minute
- Patellar reflexes are present
- Urinary output is at least 30 mL/hour over 4 hours

Withhold or delay drug if:

- Respiratory rate falls below 16 per minute
- Patellar reflexes are absent
- Urinary output falls below 30 mL/hour over preceding 4 hours

Keep antidote ready:

- In case of respiratory arrest:
  - Assist ventilation (mask and bag, anesthesia apparatus, intubation)
  - Give calcium gluconate 1 g (10 mL of 10% solution) IV slowly until calcium gluconate begins to antagonize the effect of magnesium sulfate and respiration begins.

**Table 5: Diazepam schedules for severe preeclampsia and eclampsia**

**Note:** Use diazepam only if magnesium sulfate is not available.

<table>
<thead>
<tr>
<th>Intravenous administration</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Loading dose</strong></td>
</tr>
<tr>
<td>• Diazepam 10 mg IV slowly over 2 minutes</td>
</tr>
<tr>
<td>• If convulsions recur, repeat loading dose</td>
</tr>
<tr>
<td><strong>Maintenance dose</strong></td>
</tr>
<tr>
<td>• Diazepam 40 mg in 500 mL IV fluids (normal saline or Ringer’s lactate) titrated to keep the woman sedated but rousable.</td>
</tr>
<tr>
<td>• Maternal respiratory depression may occur when dose exceeds 30 mg in 1 hour:</td>
</tr>
<tr>
<td>- Assist ventilation (mask and bag, anesthesia apparatus, intubation), if necessary.</td>
</tr>
<tr>
<td>- Do not give more than 100 mg in 24 hours.</td>
</tr>
<tr>
<td><strong>Rectal administration</strong></td>
</tr>
<tr>
<td>• Give diazepam rectally when IV access is not possible. The loading dose is 20 mg in a 10 mL syringe. Remove the needle, lubricate the barrel and insert the syringe into the rectum to half its length. Discharge the contents and leave the syringe in place, holding the buttocks together for 10 minutes to prevent expulsion of the drug. Alternatively, the drug may be instilled in the rectum through a catheter.</td>
</tr>
<tr>
<td>• If convulsions are not controlled within 10 minutes, administer an additional 10 mg or more, depending on the size of the woman and her clinical response. Be prepared to assist ventilation.</td>
</tr>
</tbody>
</table>

Abbreviation: IV, intravenous
If hydralazine is not available, give labetalol or nifedipine:
- Labetalol—10 mg IV
  - If response to labetalol is inadequate (diastolic BP remains above 110 mm Hg) after 10 minutes, give labetalol 20 mg IV
  - Increase the dose to 40 mg and then 80 mg if satisfactory response is not obtained after 10 minutes of each dose
- Nifedipine—5 mg under the tongue
  - If response to nifedipine is inadequate (diastolic BP remains above 110 mm Hg) after 10 minutes, give an additional 5 mg under the tongue.

Note: There is concern regarding a possibility for an interaction with magnesium sulfate that can lead to hypotension.

Delivery

Delivery should take place as soon as the woman’s condition has stabilized. Delaying delivery to increase fetal maturity will risk the lives of both the woman and the fetus. Delivery should occur regardless of the gestational age.

In severe pre eclampsia, delivery should occur within 24 hours of the onset of symptoms. In eclampsia, delivery should occur within 12 hours of the onset of convulsions.

- Assess the cervix
- If the cervix is favorable (soft, thin, partly dilated), rupture the membranes with an amniotic hook or a Kocher clamp and induce labor using oxytocin.
- If vaginal delivery is not anticipated within 12 hours (for eclampsia) or 24 hours (for severe preeclampsia), deliver by cesarean section.
- If there are fetal heart rate abnormalities (less than 100 or more than 180 beats per minute), deliver by cesarean section.
- If the cervix is unfavorable (firm, thick, closed) and the fetus is alive, deliver by cesarean section.
- If safe anesthesia is not available for cesarean section or if the fetus is dead or too premature for survival:
  - Aim for vaginal delivery
  - If the cervix is unfavorable (firm, thick, closed), ripen the cervix using misoprostol, prostaglandins or a Foley catheter.

ANAPHYLAXIS

- Incidence: Very rare
- Risk factor: Asthmatic, history of atopy, drug administration, latex allergy
- Clinical symptoms and signs: Dyspnea, tachycardia, hypotension, wheezing
- Management: Crystalloid infusion, adrenaline and antihistamines, hydrocortisone.

CARDIOMYOPATHY

- Incidence: One in 3,500.
- Risk factor: Pregnancy induced hypertension, twins, advanced maternal age
- Clinical symptoms/signs: Severe left ventricular failure
- Management: Urgent cardiology review.

AORTIC DISSECTION

- Incidence: One in 5,000.
- Risk factor: Marfan’s syndrome.
- Clinical symptoms/signs: Back or chest pain, dyspnea.
- Management: Urgent specialist (cardiologist, cardiothoracic surgeon) review.

DETERIORATION OF CARDIAC DISEASE

- Incidence: Variable
- Risk factor: Pre-existing cardiac disease
- Clinical symptoms/signs: Back or chest pain, dyspnea.
- Management: Urgent specialist (cardiologist, cardiothoracic surgeon) review.

STROKE

- Incidence: One in 500
- Risk factor: Any hypertension
- Clinical symptoms/signs: Change in consciousness, headache, vomiting, photophobia, neurological deficit, cardiac arrest
- Management: Urgent CT/MRI scan, neurology review.
- Subarachnoid hemorrhage can also result
- Cerebral venous thrombosis
  - Incidence: One in 10,000
  - Risk factor: Any hypertension
  - Clinical symptoms/signs: Change in consciousness, headache, vomiting, photophobia, neurological deficit, cardiac arrest
  - Management: Urgent CT/MRI scan, neurology review.

INHALED VOMIT SYNDROME
(MENDELSON’S SYNDROME)

- Definition: Gastric contents which are highly irritant, may be inhaled during induction of anesthesia, especially during pregnancy, resulting in chemical pneumonitis.
- Risk factors: The risk is higher in late pregnancy which predisposes to regurgitation of gastric contents, and when there is difficulty in intubation as happens in obese patients.
Clinical signs and symptoms: Clinical features may appear between 2 hours and 5 hours after anesthesia and include cyanosis, tachycardia, dyspnea, wheeze, crepitant rales, and decreased arterial oxygen tension.

Management: Routine use of antacids and/or epidural anesthesia can help to reduce the risk.

CARDIAC ARREST

Incidence: One in 30,000 pregnancies
Risk factors: The most frequent reasons for cardiac arrest in pregnancy and postpartum are obstetric hemorrhage and complications of severe preeclampsia. A list of common causes is shown in Table 6.
Management: Prompt resuscitation of the mother provided on the spot can save both maternal and fetal life. However, resuscitation is difficult in pregnant patients due to the physiological changes of pregnancy. Individuals involved in resuscitation must be aware of these limitations so that they can provide effective resuscitation.

MORTALITY WHAT TO DO

Inspite of all critical evaluation and meticulous management, there can be a postpartum collapse and mortality.

Patient-oriented Problems
- Nonattendance of antenatal care
- Infrequent attendance
- Delay in seeking help
- Noncompliance.

Administrative Factors
- Delay in transport from home to institution
- Delay in transport between institution
- Delay in admissions area
- Insufficient intensive care unit (ICU) beds
- Lack of appropriately trained medical officers
- Lack of communication between health workers.

Medical Person-oriented Problem
- Initial assessment incomplete
- Delayed problem recognition
Management plan/protocol: Standard protocol may not be followed at each level
- Monitoring may be improper
- Resuscitation may not be trained
- Improper documentation.

Ethical Issues
Allowing relatives to be present during resuscitation, it has been reported that family members present during resuscitation may benefit from witness in the event. However, option may be given to the relatives. Sometimes, family members may panic and cause undue stress on the staff managing the patient.
Confidentiality should not be violated specially dealing with HIV positive women.
Consent from the patient or patient’s relative is obtained; however, in an emergency situation, a doctor may administer medical treatment without consent, provided the treatment is needed to save life or avoid significant deterioration in the patient’s health (seeking patient’s consent, the ethical consideration GMC 1998).

After the Event Debriefing of the Events
Accurate documentation of all the events, timing of all resuscitative process and treatment received must be done properly for retrospective review of management. It is a good practice to inform the patient’s relatives and treating physician regarding treatment given and outcome. If the outcome is good, careful counseling should be done by gynecologist regarding future obstetric outcome, underlying medical causes and contraception.

CONCLUSION
Sudden postpartum collapse is a rare but a serious obstetric complication. This is the manifestation of varied type of pathologies in the immediate postpartum phase. This needs an immediate attention and resuscitation to maintain the ventilation, oxygenation and hemodynamic stability.
Essential investigations, on the basis of clinical judgment, are needed to establish the diagnosis of the sudden circulatory collapse. Monitoring of the CVP, ECG, arterial blood gas analysis, spiral computed tomography are helpful. Subsequent managements are to be carried out by a specialist team according to the specific pathology. Management of complications may need anticoagulants, anti-arrhythmic drugs, blood transfusion with coagulation factor replacement, anticonvulsants or thrombolysis. In some cases, surgery may be needed in the form of embolectomy or in placement of inferior vena cava filter or hysterectomy. Because of its rarity, obstetric units lack the experience in dealing with nonhemorrhagic collapse cases. ICU is mandatory in each obstetric unit for managing such cases. Anticipation of risk factors, prompt diagnosis and intensive care with experts of multidisciplinary team holds the key to save the life in this critical condition.

Emergency in Pregnancy
Antepartum Hemorrhage

INTRODUCTION

In addition to unacceptably high perinatal mortality, antepartum hemorrhage (APH) is an important contributory cause of maternal mortality and morbidity in the developing countries. Although it is not preventable, an early diagnosis and treatment can improve maternal and perinatal outcome to a large extent. Any bleeding to and from the genital tract, during pregnancy, between 20 weeks of pregnancy and delivery of fetus is known as APH. Similar bleeding prior to the age of viability is known as threatened miscarriage or threatened abortion. In the past, 28 weeks was considered the age of viability. But, currently with improved neonatal intensive care unit (NICU) facility, particularly in the industrialized world, fetal survival is possible as early as 22 weeks. Accordingly, a universal agreement is lacking regarding the age of viability. The gestational age, beyond which, the definition of APH should be considered is therefore variable from country to country. In Canada, 20 weeks and in United Kingdom (UK) 24 weeks was considered as the lower limit for defining APH. However, irrespective of the age of viability, any bleeding during the second half of pregnancy should be taken seriously and proper evaluation and treatment be given accordingly.

CAUSES

The causes of APH are diverse, varied and multifactorial (Table 1). The source of bleeding could be either fetoplacental or maternal. From the obstetric viewpoint, the two most important causes of APH are placenta previa and abruptio placenta. Together they constitute more than 50% cases of APH. However, in majority of the cases of APH, the cause remained unknown and classified under the category of indeterminate, unexplained, unclassified or idiopathic. The other rare but significant causes include vasa previa, rupture uterus and show prior to onset of labor. With a history of late trimester bleeding per vagina, it is necessary to exclude the causes of bleeding from local lesions of cervix, vagina, vulva, and also from the urinary or gastrointestinal (GI) tract.

One year study of 112 APH cases in a hospital revealed 52 cases (46.4%) of placenta previa, 28 cases of abruptio placenta (25%) and 32 cases of unclassified APH (28.6%).

Perinatal Outcome

Antepartum hemorrhage is an important cause for perinatal morbidity and mortality. In general, placental abruption

Emergency in Pregnancy

MANAGEMENT

Principles

The management of APH should be planned as general management (applicable to all cases of APH) with appropriate modification, depending on the type and severity of bleeding and specific management depending on the cause of bleeding, gestational age and condition of the fetus.

It is preferable that the management should be undertaken in a set-up having facility of round the clock blood transfusion, immediate termination of pregnancy (if required) by cesarean section (CS), neonatal resuscitation and intensive care facilities for both the mother and the neonate. If the set-up lacks those necessary facilities, the patient needs to be transferred by an ambulance to a nearby appropriate center for management. If the patient is bleeding heavily and the transport facility is not readily available or the appropriate center is quite far off, resuscitation with intravenous (IV) fluids should be started without any delay. As the fetus is safer in uterus, it is better to continue the resuscitation and transfer of the patient simultaneously. Fetal hemoglobin oxygen-binding capacity maintains adequate oxygenation until maternal partial pressures are less than 60.

Many a times, the insignificant bleeding at presentation could herald a subsequent significant bleeding at a later date and those cases also demand equal attention.

Initial management includes eliciting a proper history, physical examination of the patient as regards to fetomaternal condition and initiation of immediate treatment and investigation.

History

On duty, doctor should take quick history with specific questions to identify the background of the patient to help planning immediate and subsequent management. A proper history should include following points shown in Table 2.

### Table 2: Evaluation of history in antepartum hemorrhage cases
- Initiating factors of bleeding, if any (trauma, coitus, etc.)
- Details of bleeding: amount, character, color
- Associated abdominal pains or uterine contraction
- History of previous bleeding in the current pregnancy
- History of ruptured membranes
- Gestational age estimation (by last menstrual period (LMP) and/or first-trimester ultrasonography (USG), if available)
- Information about placental site (by the latest USG)
- Perception of fetal movements

Physical Examination

This examination should evaluate both maternal and fetal conditions shown in Table 3.

Immediate Treatment and Investigations

Irrespective of the cause, significant vaginal bleeding during pregnancy needs to be managed with rapid assessment of maternal and fetal status, fluid resuscitation, replacement of blood products when necessary, and an appropriately timed delivery. Being unpredictable in nature and having the possibility of sudden deterioration in clinical condition, even a minor bleeding may have considerable significance in pregnancy and should receive appropriate attention by the on duty obstetrician.

For management of massive obstetric hemorrhage cases, each obstetric unit must have a protocol of their own. A good interdepartmental liaison between the labor ward and the blood bank is of paramount importance. Ideally, both should be nearby. A regularly organized “fire drills” amongst all the members of the labor ward staff including the blood bank personnel helps in keeping them aware of their individual role at the time of emergency.

Immediate treatment and investigation should include the following as shown in Table 4.

Subsequent Management

After initial assessment and institution of treatment, depending on persistence of bleeding and its quantum, gestational
CHAPTER

Antepartum Hemorrhage

45

397

Types of Placenta Previa (Figs 1A to C)

Depending on the sites of implantation, placenta previa is typically divided into four grades:

- **Grade I—Low lying placenta**: Placenta is implanted into lower uterine segment, but the lower limit of it does not reach up to internal os.
- **Grade II—Marginal placenta previa**: Leading placental edge reaches but does not cover the internal os.
- **Grade III—Partial placenta previa**: Placenta partially or asymmetrically covers the internal os.
- **Grade IV—Total or central placenta previa**: Placenta covers the internal os completely.

Anatomical classifications based on endovaginal ultrasound:

- **Total**: Placenta completely covers internal os.
- **Partial**: Lower placental border does not cover but is within 30 mm of the internal cervical os.
- **Low lying**: Placental margin can be seen with endovaginal probe but is more than 30 mm away from internal os.

Summary: General

- Antepartum hemorrhage is an important cause of fetal and maternal mortality and morbidity
- Placenta previa and abruptio placenta are important causes. In majority, cause remains unknown
- The principles of management are:
  - Initial assessment of patient’s condition
  - Resuscitation of patient
  - Prolongation of pregnancy, if possible or indicated or immediate delivery for fetal or maternal indications
  - Subsequent management depends on specific cause.

**PLACENTA PREVIA**

Definition

Previa means “in front”. It is a type of placenta when at least a part of it is implanted in the lower uterine segment and in front of the internal cervical os. It is one of the leading causes of vaginal bleeding in second and third trimester of pregnancy and thereby responsible for both fetal and maternal morbidity and mortality.

Table 4: Immediate treatment and investigations

- Intravenous (IV) line is established preferably with a wide bore cannula to facilitate rapid volume replacement.
- Blood sample is obtained for hemoglobin or hematocrit estimation, and determination of grouping and typing.
- In presence of severe or continuous bleeding, at least four units of blood should be kept ready by cross-matching. Clinically, if abruptio is suspected, a coagulation profile and measurement of urea, creatinine and serum electrolytes are also performed.
- In Rh negative women, Kleihauer-Betke test is performed on maternal blood. If vasa previa is suspected, an alkali denaturation test (APT) is performed on vaginal blood to identify fetal source of bleeding.
- Pending arrival of blood, volume replacement should be started with IV fluids, initially with crystalloids and then, if necessary, by colloids.
- Soon after maternal and fetal condition is stable, an ultrasonography (USG) scan is arranged to localize placenta and to confirm or exclude placenta previa or to exclude a major placental abruption. It can also provide additional requisite information about the fetus.
- Cardiotocography may show evidences of fetal compromise, an indirect evidence of uterine irritability.

Table 5: Maternal condition following initial management

- Bleeding stopped and the pregnancy is at term
- Bleeding stopped and the pregnancy is preterm
- Mild to moderate bleeding continuing and pregnancy term or preterm
- Severe and life-threatening bleeding continuing
- Fetus distressed
- Fetus dead

Table 5: Maternal condition following initial management

- Figs 1A to C: Types of placenta previa. (A) Low placental implantation; (B) Low placental previa; (C) Complete placenta previa
Emergency in Pregnancy

Table 6: Risk factors for placenta previa

- Advanced age
- High parity
- Cigarette smoking—risk increased by 3- to 6-fold
- Cocaine use—risk increased by 2.4-fold
- Previous CS deliveries—risk increased more with number of previous CS
- Previous abortion or curettage—risk increased by 1.8-fold
- Previous manual removal of placenta
- Deficient endometrium due to presence or history of
  - Submucous fibroid
  - Endometritis
- Large placenta, e.g. multiple pregnancy

Incidence

At term, the incidence of placenta previa is 0.4–0.8% of all pregnancies. Placenta previa is a common incidental observation on second-trimester ultrasonography (USG) and found in approximately 4% cases at 20–24 weeks gestation. At term, the incidence is however reduced to only 0.4% of pregnancies. This is because of so called placental migration, resulting from differential growth of uterus and placenta.

Etiology

The exact reason for implantation of blastocyst into the lower uterine segment and subsequent development of placenta previa is unknown. Although a chance occurrence can not be ruled out, a number of well-recognized associations had been noted with placenta previa. Damage to the endometrium or myometrium due to previous uterine surgery or infection might be a contributory factor for such implantation. Significant association had been noticed between previous CS deliveries and placenta previa. A uterine scar also predisposes to morbid placenta and the risk of placenta accreta, increta and percreta increases with the number of cesarean deliveries. The incidence increases with age, parity, tobacco use and previous cesarean deliveries. Drug abuse (especially cocaine) and history of abortion (spontaneous or induced, particularly their number) are also recognized risk factors for placenta previa. Increase in number of cesarean deliveries increases the incidence of placenta previa so that it becomes almost 10% after four or more cesarean deliveries. Abruptio placenta in previous pregnancy increases the chance of placenta previa in present pregnancy. The risk of recurrence of placenta previa in subsequent pregnancy is increased by 8–10 times.

Maternal Complications

The complications are related to bleeding and its consequences. Globally, although maternal mortality had improved significantly over the years, in developing countries, wide spread pre-existing anemia, difficulties in transport and inadequacies of maternity care services are the important deterrents to improve maternal outcome comparably. In industrialized world, maternal mortality is improved to around 0.03–0.5%. The maternal risks could be summarized as follows:

- Although in up to 30% cases, there may not be any further bout of bleeding during the antenatal period, the relative risk of observed episode of bleeding is increased by 10%.
- The need for blood transfusion is increased by 10-fold.
- There is an increased likelihood ratio of retroplacental hemorrhage and placental abruption.
- Postpartum hemorrhage (PPH) is the major contributory factor of maternal mortality and is caused by inadequate occlusion of the placental venous sinuses in the lower segment in addition to bleeding from large surface area of the placental implantation site.
- Air may enter into the systemic circulation through low pressure open placental venous sinuses and lead to features of air embolism few hours after delivery.
- Increased association of morbidly adherent placenta further accentuates the bleeding and surgical complications and the need for hysterectomy.
- The probability of peripartum hysterectomy is increased by 33-fold.
- Emergency CS in a inadequately prepared patient increases the likelihood of anesthetic and surgical complications.
- Postpartum sepsis is caused by ascending infection of relatively nearby placental implantal site.
- The risk of recurrence of placenta previa in subsequent pregnancy is 4–8%.

Fetal Complications

Because of conservative management and improved neonatal care facility, perinatal mortality had improved significantly over the years, but compared to control population perinatal mortality associated with placenta previa is higher by a factor of 2.9–4.25. Perinatal mortality in industrialized world is 42–81 per 1,000 births. The causes of increased perinatal mortality and morbidity are shown in Table 7.

Presentation

The classic presentation is vaginal bleeding with the following characteristics (Table 8).

Second-trimester scan can identify asymptomatic low lying placenta. These cases need to be counseled properly mentioning the possible risk of bleeding and also the fact of so called placental migration during the course of pregnancy. In addition, 9–10% of cases of placenta previa are associated with placenta accreta, an abnormally firm attachment of the placenta to the wall of the uterus.
Table 7: Causes of increased perinatal mortality and morbidity

- Increased incidence of respiratory distress syndrome (RDS) (OR 4.94) because of increased frequency of preterm birth (almost 50%). More preterm births are associated with poor neonatal prognosis.
- Increase incidence of major congenital abnormalities (OR 2.48). The most common malformations are those of central nervous system (CNS), cardiovascular system (CVS), respiratory and gastrointestinal (GI) system.
- Perinatal mortality is also directly related to total amount of blood lost antepartum.
- Increased incidence of fetal anemia (OR 2.65)
- Increased incidence of intrauterine growth retardation (IUGR) (occurs in 16%). Although a recent data is contradictory, reduction in fetal growth velocity is a likely possibility and is due to repeated bouts of antepartum hemorrhage (APH).
- Additional fetal risks include cord prolapse and compression and sudden unexplained fetal death due to rupture of vasa previa and severe maternal hypovolemic shock.
- Fetal malpresentation.

Table 8: Presentation of vaginal bleeding

- Bleeding occurs suddenly and is usually unprovoked.
- Bleeding is usually bright red.
- Usually a painless condition and absence of pain is considered as a distinguishing point from abruptio placenta. However, some degree of uterine irritability is present in about 20% of the cases either because of associated abrasion or because of simultaneous onset of labor.
- Initial bleeding is not usually profuse. It spontaneously resolves on its own, only to recur later. First episode of bleeding is often referred to as “warning hemorrhage” or “sentinel bleed”.
- The first episode of bleeding is commonly noted at 27–32 weeks’ gestation.
- In more than 50% cases, bleeding occurs prior to 36 weeks.

**Diagnosis**

Many cases of placenta previa are diagnosed by routine ultrasound. In other cases, the initial diagnosis is made when the patient comes to the hospital with vaginal bleeding. Placenta previa is a common incidental finding on second-trimester USG and should be confirmed in the third trimester. A placenta previa is a common incidental observation on second-trimester USG and found in approximately 4% cases at 20–24 weeks gestation. At term, the incidence is however reduced to only 0.4% of pregnancies because of so-called placental migration, resulting from differential growth of upper and lower segments of uterus with the growth and development of pregnancy. Only 10% of low lying placetas identified at the 16–20 weeks USG will remain low at term. Ultrasonography is the mainstay of diagnosis of placenta previa. Transabdominal sonography (TAS) route is commonly employed. TAS is simple, safe and precise method to localize placenta with an accuracy of 93–98%. Because of focal uterine contraction or distension of bladder, false positive result is a distinct possibility. Errors in diagnosis are most likely in cases of posterior placenta previa, because of the difficulties in proper identification of lower uterine segment.

Transvaginal sonography (TVS) is considered as gold standard for localization of placenta and diagnosis of placenta previa. When the diagnosis of placenta previa is clinically suspected or remains uncertain or equivocal by TAS, TVS clarifies the situation and confirms the diagnosis (Fig. 2). TVS is safe, more accurate than TAS, does not increase the chance of bleeding and does not require full bladder and has better diagnostic accuracy with posterior placenta previa. In addition, TVS changes the diagnosis made by TAS in 26% of cases. The angle between the transvaginal probe and the cervical canal is such that the probe does not enter the cervical canal. Some advocate insertion of the probe no more than 3 cm for visualization of the placenta. Placenta previa is diagnosed on transvaginal scan when the leading placental edge is less than 3 cm away from the internal os. As an alternative to TVS, especially when instrumentation of the vaginal canal is a concern, experts in USG can utilize transperineal approach to diagnose placenta previa. This method could also be used as a complimentary to TAS. Magnetic resonance imaging (MRI) has been suggested as a safe, alternative and most accurate method to diagnose placenta previa. The high cost limits its availability. A large trial determining the efficacy and safety of the use of MRI during pregnancy has not been performed, and further investigation is required. MRI is not widely available or used and at the moment is relevant only in cases of inconclusive USG findings. It is suggested that MRI may help in confirming the diagnosis of invasive placenta and identify organ involvement associated with placenta percreta.

**Management**

The management of placenta previa is guided by the principle of expectancy; to allow the pregnancy to progress to as close to term as possible and then delivery is undertaken.

![Fig. 2: Transvaginal sonography of a complete posterior placenta previa: the placental edge covers the internal os](image)
Incidental Diagnosis of Placenta Previa

Because of the possibility of migration of placenta to upper uterine segment in more than 90% cases, expectant management is generally followed. The length by which the placenta overlaps the internal os at 18–23 weeks is highly predictive for the persistence of placenta previa. The likelihood of a previa persisting until term increases if the previa is complete, if it is present at a later gestational age or if there is a history of cesarean delivery. The length by which the placenta overlaps the internal os at 18–23 weeks is highly predictive for the persistence of placenta previa. If the overlap is less than 1.5 cm (0.6 inches) at 18–23 weeks, placenta previa typically resolves; if the overlap is 2.5 cm (1 inch) or greater at 20–23 weeks, persistence to term is likely. The likelihood of a previa persisting until term increases if the previa is complete, if it is present at a later gestational age or if there is a history of cesarean delivery.

Based on the aforesaid information, a conservative approach is logical and usually followed at home. During the interim period of expectancy, management is based on the following principles:

- Strenuous work is avoided
- Sexual intercourse is avoided
- Advised to attend hospital, if there is any bleeding
- Regular intake of hematinsics is ensured and maintained
- Placental location is again re-evaluated by USG.

If placenta previa is still present by repeat USG through transvaginal route, the same precautionary measures are followed. If placenta previa persists beyond 32–34 weeks, migration to upper segment by term is unlikely. Although, rescanning is usually followed in most of the centers, there is no evidence that rescanning “at risk” patients in the third trimester reduces adverse fetal or maternal outcome from placenta previa. Randomized trials addressing this issue are needed. Rescanning is definitely indicated in cases of persistent malpresentation and/or vaginal bleeding and TVS is preferred. Waiting beyond 37 weeks is not likely to benefit the fetus or mother. CS usually is scheduled at a gestational age that will maximize the likelihood of fetal maturity and minimize the risk of hemorrhage that may result from the normal onset of uterine contractions.

Because placenta previa may resolve to close to term, it is recommended that no decision on mode of delivery be made until after USG at 36 weeks. Women whose placental edge is 2 cm or more from the internal os at term can expect to deliver vaginally unless heavy bleeding ensues. The vaginal delivery should be attempted in a facility capable of moving the patient rapidly to cesarean delivery if necessary. Although not universally followed, documentation of pulmonary maturity by amniocentesis in women with a nonbleeding placenta previa at 36–37 weeks is performed in some centers prior to scheduled cesarean delivery.

If Presents with Bleeding

Initial management of APH (as discussed in the previous section) is instituted without delay. Depending on the severity or persistence of bleeding, gestational age, maternal and fetal condition, the options for subsequent management are: immediate delivery, expectant management and termination of pregnancy.

Following clinical situations shown in Table 9 demand immediate delivery by CS.

The mode of delivery depends on the grade of placenta previa and state of the cervix. The options are immediate CS and examination in the operation theater (OT), with or without anesthesia (“double set-up”). Cesarean route is the preferred method of delivery in most of the situations (fetal malposition or malpresentation, fetal heart rate (FHR) abnormality and major degree placenta previa) and the only option in presence of profuse bleeding. In case of a low-lying or marginal placenta previa, the descending fetal head may “ramponade” the bleeding placental edge (thereby reducing bleeding from the separated placental edge) and permit vaginal delivery.

The “double set-up” examination (Table 10) is indicated in cases of grade I or grade II anterior placenta previa or when the USG findings for localization of placenta are inconclusive.

Prerequisites for “double set-up” examination include:

- Intravenous (IV) lines started
- Cross-matched blood is available
- Examination is performed in the OT
- An experienced obstetrician should perform the examination
- Second obstetrician must be scrubbed and ready to operate

Table 9: Indications for immediate delivery

- Deteriorating condition of the mother
- Persistent heavy bleeding
- Gestational age more than 36 weeks
- Estimated fetal weight more than 2,500 g
- Fetal distress in a viable fetus
- Contractions that do not respond to medication

Table 10: “Double set-up” examination

- A sterile speculum examination is done to see the cervix. Cervix partly dilated and placental tissue is visible—placenta previa is confirmed and delivery is planned.
- If the cervical os is not dilated, vaginal fornices are palpated carefully
  - Spongy tissue felt—placenta previa confirmed
  - Fetal head felt—placenta previa excluded
- If the diagnosis is still in doubt, careful digital examination is done through the cervix
  - Soft tissue felt within cervix: Placenta previa confirmed
  - Fetal parts and membranes are felt both centrally and marginally, placenta previa is excluded.
Expectant Management

Provided the initial episode of bleeding resolves and the fetomaternal condition is stable, it is reasonable to delay delivery until fetal maturity is attained or any subsequent bouts of significant bleeding supervene. Although not universally followed, in some centers, expectant treatment is also considered even when the initial bleeding is severe and then the bleeding either stops or slows down. The goal of this expectant approach is to improve perinatal outcome by prolongation of pregnancy and several groups had reported that bed-rest is instituted with strict avoidance of any inciting factors of bleeding. Measures, including blood transfusion and administration of hematinsics, are taken to raise hemoglobin status to prepare the patient to withstand any further significant rebleeding. The aim is to maintain maternal hemoglobin at least 10 g% or hematocrit 30%. In addition to bed-rest, steroids are usually given to hasten fetal lung maturity. In Rh negative women, an injection of Rh immune globulin is also administered after performing Kleihauer-Betke test to determine the appropriate dose. In all cases of expectant management, two units of blood must be available at all times. During the expectancy period, some interventional measures were tried and/or adopted to improve maternal and fetal outcome.

Elective Cervical Cerclage

To prolong pregnancy and prevent iatrogenic prematurity due to bleeding, cervical cerclage has been proposed and tried. The Cochrane meta-analysis found that cerclage decreased the risk of premature birth before 34 weeks (relative risk = 0.45; 95% confidence interval, 0.23 to 0.87); however, it is recommended that additional studies of cerclage be performed before this clinical practice is introduced. In summary, cervical cerclage may reduce very premature births, although the evidence is not very strong.

Tocolytic Agents

Tocolytic agents may be used safely to prolong gestation if vaginal bleeding occurs with preterm contractions. Although studies using tocolytic agents show a trend toward increased frequency of bleeding episodes, neither is this bleeding significant nor does it increase the requirement of blood transfusion. Uterine contractions in presence of placental previa may be due to abruption (associated in 10% cases) and due consideration should be given to exclude abruption prior to administration of tocolytic agent.

At present, there is inadequate evidence to suggest that either in-patient or out-patient care leads to a superior outcome. On the contrary, outpatient management is appropriate for selected patients who do not have active bleeding and who can rapidly access a hospital with operative labor and delivery services. This approach is applicable to only Grade I to III placenta previa and asymptomatic Grade IV placenta previa. However, in clinical practice, frequently a combination of in-patient and out-patient management is undertaken. For a particular patient, the decision is taken by analyzing the following factors shown in Table 11.

### Table 11: Factors influencing the decision of in-patient vs out-patient management

- Each case is given due importance and individualized approach is adopted.
- History of bleeding—stopped/continuing
- Grade of placenta previa
- Patient’s social circumstances—distance of residence from the hospital, transport facility, manpower support
- Patient’s wishes
- Obstetrician’s preferred practice.
Termination of Pregnancy

Cesarean section is the recommended method of delivery in nearly all cases of placenta previa except those cases of Grade I placenta previa, where the distance between the leading placental edge and the cervix is at least 20 mm to allow vaginal delivery. CS, as an optional method of delivery, is also contributed by increased incidence of malpresentation and other obstetric factors. In cases of anterior placenta previa, it is often beneficial to perform a scan immediately prior to CS, to localize the placenta precisely and to look for any “placenta free window” so as to plan the incision at lower uterine segment during CS. In absence of such “placenta free window”, the options for access to the fetus are either transplacental approach or “classical” incision in the upper uterine segment. The former approach requires speed and may cause significant fetal blood loss. The latter approach may be associated with undue delay in delivery of the fetus, more troublesome bleeding from a partially separated placenta with resultant fetal blood loss and anoxia, along with the potential risk of scar rupture in subsequent pregnancy. However, a lower segment approach is preferred by most obstetricians. Because of inevitable fetal blood loss, cutting or tearing through placenta is avoided by many. Less retractile nature of the lower uterine segment provokes increased intraoperative bleeding through torn placental sinuses. To achieve hemostasis, following measures (Table 12) can be undertaken with variable degree of success:

- Recently, prothrombin complex and recombinant factor VII are being utilized to control massive hemorrhage with placenta previa.

Women with a history of previous cesarean delivery and placenta previa or a placenta located at the site of the previous incision are at a higher risk of morbidly adherent placenta and so, should be evaluated accordingly with color-flow Doppler imaging (Fig. 3). The method has a positive predictive value for detection of placenta accreta of 87.5%. MRI of the pelvis may help to confirm the diagnosis of an invasive placenta and delineate organ involvement in women with a placenta percreta. Nine to ten percent of cases of placenta previa are associated with placenta accreta, an abnormally firm attachment of the placenta to the wall of the uterus. Placenta accreta prevents separation of placenta from the uterine wall at the time of delivery and can induce severe bleeding thereby increasing the need for peripartum hysterectomy (>90%). This possibility needs to be discussed with the patient, prior to CS. More than 50% of patients with placenta accreta require blood transfusion. However, hysterectomy can be avoided by employing a conservative approach, wherein, the placenta is left in situ followed by either internal iliac artery ligation or uterine artery embolization or by adopting a medical approach with administration of systemic methotrexate.

When possible, the procedure should be performed electively with following preparations: adequate venous access, ready availability of blood and necessary medications and discussion about the possible need of hysterectomy in dire situations. An experienced surgeon, preferably a consultant should perform the operation or at least be readily available. Available data suggests that the risk of bleeding may be more with GA, which is contrary to the commonly held view. Accumulated evidence also indicates that regional anesthesia is a safe alternative to GA in both elective and emergency cesarean deliveries in cases of placenta previa.

Summary: Placenta Previa

- Transvaginal sonography is the most reliable diagnostic method and without any risk too.
- Postcesarean pregnancy increases the risk of placenta previa and also adherent placenta.
- Routine anomaly scan at 20–22 weeks has a high false positive and even 7% false negative rate for diagnosis, depending on whether abdominal or vaginal route of sonography is employed.

Abruptio Placenta

Definition
Premature separation of a normally situated placenta during the antenatal or intrapartum period of pregnancy is known as abruptio placentae. Approximately, 20% of all cases of APH are due to abruptio.

Incidence
Abruption has been estimated to occur in 6.5 pregnancies per 1,000 births,31,32 and up to 1.5% in all pregnancies. Many cases of abruptio remain unrecognized until delivery and in one study histological examination of placenta reveals that, the incidence is as high as 4.5%. Thus, the criteria used for diagnosis is responsible for reported wide variation in incidence (0.49–1.8%). Approximately, 50% of placental abruptions occur before 36 weeks’ gestation, resulting in adverse outcomes secondary to prematurity.33

Causative Associations
The cause of abruptio is unknown in most cases. Within few hours, however, the cause may become obvious. Various risk factors are associated with placental abruptio (Table 13).

The risk factors include chronic hypertension, preeclampsia, thrombophilies, abdominal trauma and abruptio in a previous pregnancy,34 tobacco or cocaine use.35 Chronic hypertension is associated with threefold increase in the risk of abruptio. Although maternal hypertension is considered a risk factor, there is no consensus as to whether hypertension precedes abruptio or vice versa. The other independent associations of placental abruptio include severe fetal growth restriction, prolonged rupture of the membranes, chorioamnionitis (infection of placenta and membranes), hypertension (including preeclampsia, nonproteinuric pregnancy-induced hypertension and pre-existing hypertension), cigarette smoking, advanced maternal age and unmarried status.36 Abruptio in cases of preterm premature rupture of membranes (PPROM) typically presents with bleeding followed by dribbling. Trauma, notably road traffic accidents and even domestic violence may also cause abruptio. Sudden uterine decompression after rupture of membranes or delivery of a first twin may precipitate placental abruptio.37 Placental abnormalities (especially circumvallate placenta) and increased level of alpha-fetoprotein are also associated with abruptio. Placental abruptio is twice as common in twin, than singleton pregnancies.38 The risk of placental abruptio in subsequent pregnancies is significant varying from 6% to 16.7% after one episode and increases to 25% after two such episodes. In one study, the incidence increased by at least 10-fold (incidence 4–5%).39

The association of folic acid deficiency with abruptio was not confirmed by any large prospective studies. On the other hand, the associations between abruptio and specific thrombophilias (such as factor V Leiden mutation, prothrombin gene mutation, hyperhomocysteinemia, activated protein C resistance, antithrombin III deficiency and anticardiolipin immunoglobulin G antibodies) have been reported in different literatures and this risk may be independent of the presence of preeclampsia. The presence of thrombophilias may also influence the severity of abruptio. The association between abruptio and thrombophilias, however, had not been uniformly documented in all the related studies.

Classification
Broadly, abruptio is classified into two groups: (1) revealed—where obvious bleeding is noted in the lower genital tract and (2) concealed—where entire blood is contained inside the gravid uterus without any manifestation of external bleeding. Abruptio is concealed in 20–35% and revealed in 60–65% cases.40 The concealed type is more dangerous and associated with more severe maternal and fetal complications. A more precise classification of abruptio based on the extent of separation (partial vs complete) and location of separation (marginal vs central) is as follows:
Emergency in Pregnancy

Class 0: is asymptomatic. Diagnosis is made retrospectively by finding an organized blood clot or a depressed area on a delivered placenta.

Class 1: is mild and represents approximately 48% of all cases. Characteristics include the following:
- No vaginal bleeding to mild vaginal bleeding
- Slightly tender uterus
- Normal maternal blood pressure (BP) and heart rate
- No maternal or fetal compromise

Class 2: is moderate and represents approximately 27% of all cases. Characteristics include the following:
- No vaginal bleeding to moderate vaginal bleeding
- Moderate-to-severe uterine tenderness with possible tetanic contractions
- Maternal tachycardia with orthostatic changes in BP and heart rate
- Fetal compromise or distress
- Hypofibrinogenemia (i.e. 50–250 mg/dL)

Class 3: is severe and represents approximately 24% of all cases (0.2% of all pregnancies). The characteristics are:
- No vaginal bleeding to heavy vaginal bleeding
- Very painful tetanic uterus with stony hard consistency
- Maternal shock
- Hypofibrinogenemia (i.e. <150 mg/dL) and coagulopathy
- Fetal death.

Maternal Risks

- Maternal mortality: Placental abruption is a recognized cause of maternal death, especially in resource poor settings and developing countries. The maternal mortality rate is approximately 1%.
- Hypovolemic shock: As a result of severe maternal blood loss, hypovolemic shock is the major immediate maternal risk. Because of concealed bleeding, blood loss is often underestimated.
- Coagulopathy/disseminated intravascular coagulation: There may also be clinical and hematological evidence of disordered blood clotting as thromboplastin are released by placental damage and coagulation factors are consumed in the enlarging retroplacental clot at a rate that is faster than the body’s ability to replace them.
- Postpartum hemorrhage: It can result from coagulation failure or from couvelaire uterus (a condition, where blood sips into the myometrium and impairs its ability to contract).
- Renal failure: Acute renal failure may result from either hypovolemia or disseminated intravascular coagulation (DIC) and may be seen later in the forms of either acute tubular or cortical necrosis.
- Ischemic necrosis of distal organs (e.g. hepatic, adrenal, pituitary) is the result of severe prolonged hypotension.

Fetal Risks

- Perinatal mortality rate of abruptio is 119 per 1,000. It varies from 4.4% to 67.3% depending on the severity of the condition and neonatal care facilities. More than 50% of perinatal deaths are stillbirths. Neonatal death occurs in 10–30% of cases. Approximately, 50% of placental abruptions occur before 36 weeks of gestation, resulting in adverse outcomes secondary to prematurity.
- The causes of perinatal deaths include prematurity, congenital malformation, intrauterine growth restriction (IUGR) and fetal hypoxia. DIC may result from the release of thromboplastin into the maternal circulation with placental separation. This occurs in about 10% of abruptions indicating severe abruption and is more common with fetal death.
- Fetal growth restriction is noted in 80% of infants born before 36 weeks of gestation.
- The rate of congenital malformation is increased by twofold to threefold.
- Significant fetal bleeding may cause neonatal anemia.
- The fetomaternal complications are dependent upon severity of hemorrhage, extent of placental separation, health status of mother and fetus, gestational age and effectiveness of interventions.

Clinical Presentation

Placental abruption may present with a variable combination of vaginal bleeding, abdominal pain, uterine contraction, shock or fetal distress depending on the degree of separation of placenta.
- Vaginal bleeding may or may not be obvious (“revealed” or “concealed” variety).
- Variable degree of pain over the uterus is a prominent feature and is continuous in nature.
- Uterine contractions may start and cause additional, intermittent, pain.
- Faintness and collapse with or without signs of shock may occur.
- Typically, the uterus is extremely hard and tender, without any relaxation.
- Fetal parts are difficult to palpate.
- Fetal heart may not be audible if death has occurred.
- Mild placental detachment: It may not be demonstrable on ultrasound as the blood clot is not easily distinguishable from the placenta.
- Moderate placental detachment and hemorrhage: At least one quarter of placenta has become detached and less than 1,000 mL of blood lost. There may be abdominal pain and tender uterus, mother may be in shock, fetus may be hypoxic and may show abnormal heart rate patterns.
Severe placental detachment and hemorrhage: At least 1,500 mL of blood lost, shock usual, uterus firm-to-hard and very tender. Fetus is almost always dead. Hypotension in one-third of cases, but may be normal in spite of shock. Coagulopathy is common. The presenting symptoms of abruption are as follows: vaginal bleeding—70–80% (characteristically dark and nonclotting), abdominal or back pain and uterine tenderness—70%, fetal distress—60% (in grade I and II cases), abnormal uterine contractions (e.g. hypertonic, high frequency)—35%. Uterine contractions are often difficult to differentiate from pain of abruption. Nearly 50% of the patients with abruption are in established labor. Fetal death (in grade III it is inevitable by definition) occurs in 15% cases.

Pathogenesis

It is thought that abruption is caused by degenerative changes in the spiral arterioles, leading to decidual necrosis. Following this, the vessels can rupture and bleeding ensue and ultimately forms a retroplacental clot. Placental abruption can be a self-extending process with the accumulating blood clot causing more separation and, thus more hemorrhage, until the edge of the placenta is reached. After this, blood can escape through the potential space between the chorion and the decidua until it reaches the cervix. Blood can also reach the amniotic cavity (by disrupting the placenta, producing blood stained amniotic fluid) and the myometrium (causing the bruised, so-called “couvelaire uterus”). There is usually severe fetal hypoxia associated with sizeable placental separation, and sudden fetal death is common.

Diagnosis

Placental abruption is essentially a clinical diagnosis. Features of moderate to severe abruption are suggestive. In mild cases, diagnosis is often suspected and confirmed after delivery by demonstration of a retroplacental clot indenting the maternal surface of placenta. Placental abruption can cause FMH. So, Kleihauer test could be diagnostic in mild and silent cases.

Ultrasound imaging has a much smaller role in the diagnosis. The sensitivity of USG for detection of abruption is only 24%. USG may not be helpful in diagnosing acute severe abruption, as the acoustic characteristics of a fresh retroplacental clot are similar to those of placenta and differentiation is difficult. In less severe cases where the pregnancy is allowed to continue, the clot becomes hyperechogenic within 1 week and sonolucent within 2 weeks and therefore more obvious by USG (Fig. 4).

Ultrasonography helps in excluding placenta previa and fetal congenital abnormality in addition to detecting fetal viability, number, presentation, estimated fetal weight and gestational age. The cases managed expectantly, can be monitored with USG by determining the size of hematoma, its location and change in size over time. This information may help to decide the time of delivery in mild cases managed expectantly.

Management (Flow Chart 1)

The management depends on:
- Severity of the condition
- Maternal condition
- Fetal condition
- Gestational age
- Associated complications.

The management can be divided into:
- General measures
- Specific measures.

The traditional, main principles of clinical care of a woman with placental abruption include:
- Adequate maternal resuscitation
- Assessment of fetal condition
- Adequate analgesia for pain relief
- Early delivery
- Adequate blood transfusion
- Monitoring of maternal condition.

Early Delivery

Early delivery is life saving for the fetus. In one case series, 30% of perinatal deaths occurred within 2 hours of admission. A decision-to-delivery interval of 20 minutes or less resulted in improved neonatal outcomes in a case-control study of severe abruption. Acute blood clots and the placenta are
hyperechoic on USG and is difficult to distinguish from one another. So, the definitive management should never be delayed for confirmation of diagnosis by USG.\(^{44}\)

If the fetus is already dead, as is often the case, vaginal delivery should be the goal.\(^{48}\) It has been suggested that in some cases of severe abruption, high levels of fibrin degradation products might inhibit uterine contractions and make vaginal delivery difficult to achieve.\(^{49}\) This might contribute to atonic PPH as well. Most women with abruption and DIC deliver vaginally. However, if surgical intervention is required at any point of time, measures to be taken to rapidly correct the coagulation defect by transfusion of fresh blood, fresh frozen plasma (FFP) and cryoprecipitate. To achieve vaginal delivery amniotomy is usually preferred. It not only accelerates labor, but is also believed to reduce the incidence of coagulopathy by reducing intra-amniotic pressure and thereby minimizing the entry of tissue thromboplastin into the maternal systemic circulation. Augmentation with oxytocin may be necessary in some cases. To identify fetal distress early, continuous fetal monitoring should be performed during vaginal delivery. A nonreassuring fetal heart tracing necessitates rapid, usually cesarean, delivery.\(^{57}\) As 15.4% of live born infants of abruptio do not survive,\(^{50}\) choosing a particular method of delivery in cases of live fetus may not always be very easy. The study that shows 52% perinatal mortality following vaginal delivery as compared to 16% following CS, favors CS as preferred option.\(^{51}\) A shearing force produced by uterine contraction, during vaginal delivery, may aggravate the chance of further placental separation. So, even an apparently normal fetus runs the risk of compromised oxygen supply during labor. In fact, it has been recommended that, if the baby is alive and the gestation not so preterm as to make fetal survival extremely unlikely, delivery should be by CS.\(^{52}\)

Initial management includes rapid stabilization of maternal cardiopulmonary status and assessment of fetal well-being. Prompt treatment and monitoring of the mother is essential. Maternal vital signs (pulse, BP, respiration rate) along with central venous pressure (CVP), urine output, vaginal bleeding, etc. are monitored continuously. Treatment of hypovolemic shock, if needed, should be initiated early and maintained vigorously with appropriate monitoring. In absence of fetal heart sound, it is anticipated that a massive-concealed bleeding had already taken place and traditional teaching advises transfusion of at least two units of blood. Coagulation parameters are also monitored in this situation and also when coagulopathy is suspected. As some degree of coagulopathy is expected in about 30% of severe cases of placental abruption, quick identification and treatment of

Abbreviation: EFM, electronic fetal monitoring
the condition are important. The best treatment for DIC, as a complication of placental abruption, is immediate delivery along with ancillary measures suggested by the hematologist. Maternal stabilization requires serial evaluation of the hematocrit and coagulation studies to determine whether DIC is present. Fetal condition is also monitored intermittently or continuously, as required. Because the unpredictable nature of abruption does not allow for controlled trials, the management remains empiric. Cochrane review found no randomized controlled trials assessing interventions for placental abruption that met inclusion criteria.

Expectant Treatment

In selected patients, with an aim to improve fetal maturity, expectant treatment is considered provided the following criteria are satisfied:

- Vaginal bleeding—slight
- Abdominal pain—mild and localized
- Uterus—relaxed and not irritable
- Fetal heart rate—normal
- Maternal condition—hemodynamically stable.

The treatment is continued with appropriate monitoring of fetal condition clinically and by investigations [cardiotocography (CTG), biophysical profile and Doppler velocimetry] as available. The timing of delivery was decided by:

- Any further episodes of vaginal bleeding
- Gestational age
- Fetal condition
- Neonatal care facilities.

Despite the lack of evidence, induction of labor is often advocated in patients at term because of the possible deterioration in placental function in patients even in absence of any acute or chronic fetal compromise being documented. For expectant treatment, routine admission of these patients lacks any concrete evidence. If any retroplacental clot is detected by USG, serial scan may help to monitor the size and change in echogenicity of the clot. Any deterioration of fetal condition demands immediate delivery. Some cases of mild abruption may be associated with labor. In such cases, it is difficult to determine what precedes the other. Although tocolysis is generally contraindicated, the only possible role of tocolysis is in cases of mild abruption before 34 weeks of gestation, is to allow administration of corticosteroids.

Prevention

Randomized controlled trials of sufficient power are required to assess interventions (diet, vitamin supplements and antithrombotic therapy) to prevent abruption. By reducing cigarette smoking, drug abuse and domestic violence, it is possible to reduce the incidence of abruption with intrapartum treatment of magnesium sulfate in cases of preeclampsia.

Summary: Abruptio Placenta

- A variety of associations are noted
- Diagnosis is essentially clinical
- Ultrasonography has small role in diagnosis. Sonography primarily is utilized for excluding placenta previa and monitoring retroplacental clot and fetal conditions during expectant treatment.
- Management depends on grade. Vaginal delivery in dead fetus and CS in live fetus is usually performed.
- Correction of coagulopathy is essential prior to embarking on delivery.
- Major risk factors include intrauterine device (IUD), maternal DIC and renal failure.
- Recurrence risk is 6–17% after one episode and almost 25% after two episodes.

UNCLASSIFIED (UNDETERMINED) ANTEPARTUM HEMORRHAGE

It is the most common cause of APH and the diagnosis is essentially made by exclusion of placenta previa and abruptio placentae and other obvious causes. The patient usually presents with painless bleeding which is usually mild in nature and settles spontaneously. Marginal sinus rupture appears to be the most common cause of bleeding in cases of undetermined APH. The bleeding is usually painless.

Causes

Although the cause remains unknown in majority of the situations, in a proportion of these cases, the cause may become evident later on and it includes circumvallate placenta, marginal sinus rupture, “show”, trauma, cervicitis, genital tract tumors, genital infections, vulval varicosities and vasia previa. Unrecognized cases of minor placenta previa or mild abruption, diagnosed only after delivery, are also included in the list of causes of undetermined APH.

Risks

The main concern about unclassified vaginal bleeding is their association with an increased risk of preterm delivery and a small increase in the risk of fetal congenital abnormality.

Management

Each case is managed with individualistic approach. Anti-D prophylaxis is offered to all Rh negative women. Once the diagnosis is reasonably established by exclusion of more important causes (not necessarily more common) the management depends on the following conditions:
Emergency in Pregnancy

408

- **Nature of bleeding:** Persistent or recurrent
- **Severity of bleeding:** Mild or heavy
- **Gestational age of the fetus:** Term or preterm
- **Fetal condition:** Good or distressed
- **Fetal congenital abnormality:** Present or not
- **Presumed cause:** If possible to ascertain

The management options are either immediate delivery or expectant. The mode of delivery depends on the following conditions:
- State of the fetus
- Fetal lie and presentation
- Cervical condition
- Any other associated high-risk factor.

Once the significant causes of APH are excluded, there is no obvious advantage in managing such patients in the hospital. The patient can be monitored with appropriate advice and to attend hospital immediately, should any emergency arises. The general tendency is to discharge the patient from hospital once the bleeding stops for at least 24 hours.

**VASA PREVIA**

**Introduction**

Vasa previa is the velamentous insertion of the umbilical cord into the placental membranes overlying the lower uterine segment. As a result, the fetal vessels appear between cervix and the presenting part. Despite being very rare in incidence (0.03%), associated very high perinatal mortality made rapid intervention essential for fetal survival.

**Risk Factors**

Risk factors for vasa previa include in vitro fertilization, placenta previa, and bi-lobed and succenturiate-lobed placentas.

**Presentation**

Vasa previa typically manifests as unanticipated bleeding at the time of amniotomy or spontaneous rupture of membranes.

**Diagnosis**

The condition is considered when fetal vessels are seen or felt during vaginal examination. Rarely, vessels are palpated in the presenting membranes, prohibiting artificial rupture of the membranes and vaginal delivery. Antenatal diagnosis is possible by color Doppler visualization of fetal vessels by endocavity USG. CTG shows characteristic sinusoidal pattern or baseline fetal tachycardia or bradycardia.

The hemorrhage is fetal blood, and exsanguination can occur rapidly. Alkali denaturation test (APT) (based on the principle of fetal hemoglobin’s ability to withstand alkali denaturation) confirms the fetal source of bleeding. A blood sample from the vaginal vault may be obtained to check for fetal blood cells or fetal hemoglobin.

**Management**

Suspicion, diagnosis and immediate delivery are the crucial steps in the management of vasa previa. Delivery by immediate lower segment cesarean section (LSCS) is the only way to salvage the fetus. Delivery should not be deferred for confirmation of fetal blood in women with severe hemorrhage or when CTG is nonreassuring.

Management guidelines for vasa previa:
1. Emergency cesarean section in the presence of bleeding
2. Elective cesarean section prior to the onset of labor
3. Admission to hospital with appropriate neonatal facilities from 28 to 32 weeks of gestation
4. Corticosteroids for fetal lung maturity
5. Laser ablation in utero may be tried in well equipped centers.

**Prevention**

There are no strategies for primary prevention of vasa previa. Theoretically, the complications of vasa previa could be avoided by antenatal screening of high-risk women and by performing CS at 37–38 weeks when vasa previa is present. Screening can be carried out with transvaginal color-flow Doppler to identify the presence of vessels in the fetal membranes. Although it has been suggested for women at increased risk, there is no evidence that screening in a general population changes outcomes, and because the condition is rare (one diagnosis per 5,215 screenings), this approach is also cost prohibitive.

**Fetal Risks**

Studies demonstrate a 33–100% rate of perinatal mortality secondary to vasa previa.

**Summary: Unclassified Bleeding**

- Diagnosis is made by exclusion of other causes
- Vasa previa must be confirmed or excluded
- Increases the overall risk of adverse perinatal outcome.

**REFERENCES**

Tumors During Pregnancy: Management

**TUMORS ARISING FROM REPRODUCTIVE ORGANS**
The following tumors can arise from the reproductive organs:
- Ovarian tumor
- Fibroid tumor
- Carcinoma of cervix.

**TUMORS ARISING FROM NONREPRODUCTIVE ORGANS (INTRA-ABDOMINAL)**
The following tumors arise from nonreproductive organs (intra-abdominal):
- Omental cyst
- Broad ligament tumors
- Parovarian cyst
- Retroperitoneal tumor.

**TUMORS ARISING FROM EXTRA-ABDOMINAL ORGANS**
The following tumors can arise from extra-abdominal organs:
- Breast cancer
- Non-Hodgkin’s lymphoma
- Peripheral primitive neuroectodermal tumor.

**OVARIAN TUMORS DURING PREGNANCY**
Tumors which can arise from ovaries during pregnancy are as follows:
- Teratoma (90%) mature, immature and with malignant germ cell tumor components
- Dysgerminoma, embryonal carcinoma, endodermal sinus, yolk sac tumor, choriocarcinoma, gonadoblastoma, polyembryoma
- Epithelial origin—serous adenoma, mucinous cystadenoma.

**Diagnosis**

**Symptoms**
Patients may come with amenorrhea along with dyspnea, undue enlargement of abdomen, retention of urine, and occasionally acute abdomen. Lump abdomen, pain and fever may be associated after delivery.

**Signs**
During early pregnancy cystic mass is detected apart from pregnancy whereas in late pregnancy with tumor lying above the pelvic brim two separate masses, one being the tumor commonly lying at the loin and other containing the fetus having intermittent contractions were found.
Investigations
In addition to blood and hormonal profile, ultrasonography, computed tomography scan or magnetic resonance imaging (MRI) can be advocated to confirm diagnosis. Sonographic features help to differentiate the benign from the malignant lesions, i.e. septa more than 3 mm, solid areas, ascites and irregular inner wall.
- CA-125 and DNA ploidy test are also helpful to know malignant nature of tumors.

Effect of Ovarian Tumors on Pregnancy and Labor
- Abortion and preterm labor in large and complicated tumors
- Pressure symptoms to bladder and rectum
- Malpresentations and nonmanagement
- Obstructed labor: If a pedunculated tumor is impacted in the pelvis.

Effect of Pregnancy and Labor on Ovarian Tumors
- Torsion is the most common complication particularly in pedunculated tumors that lie above the pelvic brim. It is more common during puerperium than pregnancy due to:
  - Lax abdominal wall
  - Large intra-abdominal space after birth allows free mobility of the tumor
- Hemorrhage
- Rupture
- Infection
- Rapid growth.

Management
During Pregnancy
- Cyst less than 6 cm in diameter is left and followed up by periodic examination and ultrasound as it is usually a functional corpus luteum cyst
- Cyst of 6 cm or more in diameter:
  - Discovered in the first half of pregnancy: It is removed after the twelfth week when the placenta is formed so there is less liability for abortion
  - Discovered in the second half of pregnancy: It is left to be removed in the first week of puerperium
- Complicated or malignant tumors are removed immediately irrespective of the duration of pregnancy
- In case of twisted ovarian tumor—untwisting to be followed by one side ovariectomy/ovarian cystectomy. In borderline tumor, ovariectomy is the choice of treatment. In case of suspected malignancy, unilateral salpingo-oophorectomy along with ovarian biopsy in opposite ovary. Counseling regarding the potential risk is to be properly implemented.

During Labor
- If the tumor lies above the pelvic brim—causing no obstruction—vaginal delivery is allowed and tumor is removed in the first week in puerperium.
- If the tumor is impacted in the pelvis causing obstruction—cesarean section with immediate removal of the tumor is done.

During Puerperium
Tumors discovered for the first time should be removed immediately for fear of torsion. In case of bilateral salpingo-oophorectomy—in vitro fertilization with ovum donation it to be advised. In few cases, chemotherapy is advocated.

Effect of Pregnancy and Labor on Fibroid
- Abortion: Particularly in submucous myomas due to:
  - Distortion of the uterine cavity,
  - Affection of the decidual development,
  - Affection of the vascular supply to the implanted ovum
- Ectopic pregnancy: If it interferes with the passage of the ovum
- Incarceration of retroverted gravid uterus in case of posterior wall fibroid
- Placenta previa due to interference with implantation of the ovum in the upper uterine segment
- Malpresentations
- Abdominal discomfort if the tumor is large
- Torsion of the uterus is very rare in subserous fundal myoma
- Premature labor due to premature contraction of uterus
- Nonmanagement in case of cervical fibroid (both anterior and posterior)
- Prolonged labor: Inertia may be present due to interference with normal uterine contractions
- Obstructed labor: In cervical myoma or pedunculated subserous myoma impacted in the pelvis
- Postpartum hemorrhage due to:
  - Interference with uterine retraction
  - Increased vascularity
- Subinvolution of the uterus due to large sized uterus and delayed involution
- Inversion of the uterus—rare
- Puerperal sepsis due to subinvolution and ascending infection.

Effect of Pregnancy and Labor on Fibroid
- Increase in size due to:
  - Edema and increased vascularity
  - Hypertrophy of the uterine muscles
• Softening due to edema and increased vascularity
• Red degeneration
• Torsion of a pedunculated myoma
• Internal hemorrhage from rupture of a surface vein
• Infection supervenes due to bruising during labor
• Extrusion of submucous myoma may rarely occur in puerperium.

Management

During Pregnancy

• No treatment is indicated in the majority of cases
• Myomectomy carries the risk of abortion and severe hemorrhage so it is indicated in the following conditions only:
  - Red degeneration which is not responding to the conservative treatment in the form of:
  - Rest, analgesics, antibiotics to guard against secondary infection
  - Give progesterone before and after the operation, and remove the affected tumor only
  - Torsion of a pedunculated myoma
  - Internal hemorrhage from rupture of a surface vein.

During Labor

• If the myoma lies above the pelvic brim not causing obstruction, vaginal delivery is allowed and myomectomy is done after 3–6 months, if indicated.
• If the myoma lies in the pelvis causing obstruction cesarean section is indicated, but myomectomy is contraindicated.

Postpartum

• Give prophylactic antibiotics
• Observe for postpartum hemorrhage.

Management of Cancer Cervix with Pregnancy

Premalignant Lesions

In women with preinvasive lesions confirmed on histology, a close follow-up throughout the pregnancy must be maintained with cytology and colposcopy every 6–8 weeks, and biopsy performed if there is suspicion of progression of disease. When 62 women with high-grade squamous intraepithelial lesion (HSIL) were followed, the lesion regressed in 50% (complete regression in nearly half of these), persisted in 40.3% and progressed to microinvasive carcinoma in 9.7% (6 cases). Of the 82 women followed during pregnancy with a diagnosis of low-grade squamous intraepithelial lesion, complete regression occurred in 48.8%, persistence in 29.2% and progression to HSIL in 22%.

Microinvasive Carcinoma

Women with suspected invasion on cytology or colposcopy must be treated with conization. In 23 women, who underwent conization for suspect early invasion, there were six cases (26.1%) of microinvasive carcinoma and 17 cases (73.9%) of HSIL. One pregnancy aborted 2 days after the conization. Cone biopsies, as explained earlier, taken in pregnancy are shallower, therefore positive margins are common in pregnancy. Re-evaluation must be done 8 weeks postpartum and retreatment done if required.

Carcinoma of the Cervix

This involves one of the most difficult decisions in all obstetrics. The case for radical hysterectomy is a strong one in gravid carcinoma of the cervix. The operation is likely to cause considerable blood loss, but is facilitated technically by the great ease with which the tissue planes can be dissected. The chances of encountering an operable stage or early stage disease are high in pregnancy as nearly 75% are diagnosed with stage I disease.

The treatment plan would depend on a number of factors: the period of gestation, the stage of the disease, and the desire to continue pregnancy and preserve future fertility. Accurate staging is important keeping the pregnancy in view. Imaging involving the least radiation to the fetus should be employed. An ultrasound can be done to exclude liver and urinary tract involvement and an MRI may be helpful in detecting extension of disease in the pelvis and lymphadenopathy. An X-ray chest can be performed with abdominal shielding in advance disease.

When diagnosed in early pregnancy, (an arbitrary upper limit varying between 12 weeks and 16 weeks is taken), definitive treatment for the disease must be instituted disregarding the pregnancy. When the diagnosis is made in late second or third trimester, where fetal maturity can be obtained within 6–12 weeks, an informed decision to postpone treatment for cancer may be taken. This may be
supplemented with neoadjuvant chemotherapy antenatally, in advance cases, to reduce the risk of disease progression while waiting for fetal maturity.

*Early stage disease (Ia, Ib1, IIa):* The options available for treatment of stage Ia with positive cone margins or early invasive disease before 12–16 weeks are radical hysterectomy and pelvic lymphadenectomy with the fetus in situ, or radiotherapy. External beam radiotherapy can be started with fetus in situ followed by intracavitary brachytherapy following abortion. Abortion occurs spontaneously in most cases, otherwise surgical evacuation can be performed. Surgery is preferred as the treatment of choice in young women as it prevents radiation-associated morbidity, and ovarian function can be preserved. In advance pregnancy, treatment may be delayed after counseling the patient. A caesarean radical hysterectomy with pelvic lymphadenectomy can be performed as soon as the fetus can be salvaged. Antenatal steroids to the mother would help fetal lung maturation.

*Late stage disease (Ib2, IIb, IIIb):* Treatment of pregnant women with late stage disease should be planned with a multidisciplinary approach. The treatment of locally advance cervical cancer is radiotherapy with or without chemotherapy. In early pregnancy, radiotherapy can be started with fetus in situ, as described for early stage disease. In late pregnancy, where fetal maturity has been attained, the fetus should be delivered by cesarean section. Whole pelvic external radiation may be started immediately postpartum followed by intracavitary irradiation. If the mother does not wish to terminate pregnancy, and the fetus is immature, the option of neoadjuvant chemotherapy may be discussed with the mother to postpone definitive treatment, explaining the risks of teratogenesis and fetal growth restriction.

---

**Cesarean Versus Vaginal Delivery**

Though there are no prospective trials to evaluate abdominal versus vaginal delivery, cesarean section is almost universally recommended for women with invasive carcinoma cervix for the fear of hemorrhage and dissemination of malignant cells as a result of cervical dilatation. Additionally, cases of recurrence at episiotomy site have been reported after vaginal delivery. Although metastasis may occur at the abdominal scar after abdominal delivery, the risk appears to be less than that of vaginal delivery. Women with premalignant lesions and very early invasive cancers with negative margins on a cone biopsy may consider vaginal delivery.

---

**TUMORS ARISING FROM NONREPRODUCTIVE ORGANS (INTRA-ABDOMINAL)**

*They include:* Omental cyst, broad ligament cyst and paraovarian cyst retroperitoneal tumor.

These groups of tumors are occasionally found:
- During ultrasound scanning
- During cesarean section, or
- During laparotomy

*Treatment will depend on:*
- Type of tumors
- Complications (if any), during pregnancy, labor or after delivery. Each case deserves individual consideration on its own merit.
INTRODUCTION
Approximately, 0.2–2.2% of pregnant women requires surgery not related to the gestation itself. In addition, there are no reliable estimates of how often pregnancy is present during the treatment of various surgical conditions, and especially traumatic injuries, which remain the leading cause of maternal and fetal morbidity and mortality. For optimal care of these patients, both surgeons and obstetricians must be familiar with the effects of anesthesia, surgery and trauma on pregnancy, and conversely, how pregnancy may alter the course of surgical diseases.

MATERNAL PHYSIOLOGIC CHANGES RELEVANT TO SURGERY
Gestational changes of importance to surgeons occur in the cardiovascular, pulmonary, hematological, gastrointestinal (GI) and renal systems. Knowledge of these changes allows the physician to interpret findings and laboratory data and to respond appropriately, to alterations in maternal homeostasis.

Cardiovascular Changes
The most obvious cardiovascular changes during pregnancy are those in the traditional vital signs.

- The pulse rate gradually rises to a plateau of 90 beats per minute near the 32nd week of pregnancy. The heart rate depends upon the patient’s position, with the maximum occurring while standing. In contrast, the blood pressure decreases until the 16th–20th week when systolic and diastolic pressures are 5–10 mm Hg and 10–15 mm Hg lower, respectively, than in the nonpregnant state. In a pregnant patient presenting with a surgical illness, this relative tachycardia and hypotension compared to the non pregnant state must not be misinterpreted as early hypovolemic shock.
- Cardiac output rises progressively during early gestation. By the second trimester, it attains levels 30–50% above nonpregnant values. This increase is accompanied by a 15% increase in oxygen consumption above that seen in the nonpregnant state.
- The blood volume increases during pregnancy, with plasma volume increasing more than the red cell mass. The increment in plasma volume is approximately 1.0–1.5 L, and occurs mainly early in pregnancy so that it peaks by 32 weeks’ gestation. The red cell volume only increases by approximately, 300–500 mL, so that hematocrit and hemoglobin fall to a mean of 31% and 10.5 g/dL by the end of the gestation. Greater increases in both plasma volume and red cell mass occur with multiple gestations.
- In addition to receiving a great proportion of the cardiac output, the gravid uterus can exert profound mechanical effects on the circulation during late pregnancy. When patients are placed in the supine position, the uterus may compress the vena cava and cause decreased venous return of blood from the lower extremities. In addition, the uterus may compress the aorta and thus decrease iliac artery flow. Both the arterial and venous obstructions decrease uterine perfusion particularly when compensatory reflexes are blunted by narcotics or anesthesia, the supine position
may result in profound hypotension and markedly decreased uterine blood flow. This hypoperfusion can be disastrous to the fetus. Therefore, the pregnant patient should never be kept in the supine position. This can be avoided by rotating the patient to the left side with the right hip elevated approximately 15° and the uterus manually displaced to the left.

While the cardiovascular changes of normal pregnancy may mimic congestive failure, they may mask early hypovolemic shock. With blood volume increased, 40–50% above non-pregnant levels, clinical signs of hypovolemia such as tachycardia and hypotension may not develop until the patient has lost 30–35% of her blood volume. Thus, uterine blood flow and fetal oxygenation may decrease significantly, long before maternal blood pressure begins to fall. Early recognition of hypovolemia and prompt fluid resuscitation is essential to maintain uterine perfusion. In the presence of hypovolemia, vasoconstrictors may maintain maternal blood pressure while constricting the uterine arteries and further increasing fetal hypoxia. Vasopressors are beneficial only if the increase in cardiac output and perfusion pressure offsets the vasoconstriction in the uterine bed.

Respiratory Changes

Although the diaphragm is elevated during pregnancy, the ribs are displaced outwards.

- The net result is little change in either total lung volume or vital capacity
- However, functional residual capacity is lowered by 15–20% by the end of the fourth month
- Minute ventilation, increases by 40–50%, mainly through an increase in tidal volume. These changes in ventilatory pattern begin in the first trimester
- As a consequence of this hyperventilation, arterial oxygen tension rises slightly to near 105 mm Hg
- However, in one-quarter of all women it may decrease slightly upon assumption of the supine position
- Carbon dioxide tension falls to approximately, 30 mm Hg
- Although renal compensation reduces serum bicarbonate by about 4 mEq/L, arterial pH rises slightly to 7.44.
- Failure to appreciate these normal changes in arterial pH and carbon dioxide tension can lead one to miss an early acidosis or overlook impending respiratory failure.

Pregnancy also results in increased respiratory secretions, with the epithelial lining of the respiratory tract being congested and engorged. Thus, care must be taken during intubations to avoid both hypoxemia and airway trauma. To achieve this, one often must use a smaller-than-usual endotracheal tube. Because of these physiologic changes, problems with airway management are important contributors to maternal morbidity.

Gastrointestinal Changes

Particularly, in the third trimester, pregnant patients are at risk for aspiration during periods of sedation or induction of anesthesia.

- Gastric motility is decreased during pregnancy, and as a consequence, gastric emptying is delayed.
- Because of generalized muscular relaxation, the lower esophageal sphincter is less competent.
- Although the secretion of gastric acid is decreased, nasogastric tube decompression should be considered before the induction of anesthesia.

During pregnancy a history of abstinence from food and drink is not a reliable indicator of an empty stomach.

Changes in Coagulation

- Pregnancy is marked by hypercoagulable state, attributable to increases in coagulation factors V, VII, VIII, IX, X and XII.
- Fibrinogen increases the most, nearly doubling during pregnancy. Plasma fibrinolytic activity decreases because of placental inhibition.
- These coagulation changes, in combination with the increased venous pressure in the lower extremities, increase the risk of thromboembolic disease six times above that of nonpregnant women.

ANESTHESIA DURING PREGNANCY

The concerns related to the use of anesthetic agents, during pregnancy include teratogenicity or fetal toxicity of the anesthetics, and possible effects on the mother and fetus due to alterations in maternal physiology. Although these concerns are real, current evidence suggests that a much more serious threat to both mother and fetus is the severity of the surgical disease under treatment. In addition, there is great difficulty in distinguishing the effects of anesthetics or surgical manipulations from the effects of the illness.

Teratogenicity

Before implantation at 14 days, insults to the concepts generally, result either in death of the embryo or no ill effect. Organogenesis occurs in the 45 days after implantation. During this time, the embryo is vulnerable to non-lethal damage. After the period of organogenesis, the occurrence of structural anomalies is unlikely. However, any risk is unacceptable if it is unnecessary, so that elective surgery should be avoided if possible, during the period of fetal organogenesis (15–56 days gestation). Currently, most halogenated compounds and nitrous oxide are thought to be safe during human pregnancy.
Effects on Maternal Physiology

Given the physiologic changes of normal pregnancy it follows, that anesthetic techniques which cause vasodilatation may compromise uterine oxygen delivery, particularly in a volume depleted patient. Thus, the risks of sympathetic blockade from spinal and epidural anesthesia are increased during pregnancy.

Controlling ventilation and altering maternal blood gas tensions are not without risk. In humans, hypoxia induces vasoconstriction in most vascular beds and a fall in systemic vascular resistance. The exception is the uterine bed in the pregnant patient. Maternal hypoxia or a marked maternal respiratory acidosis induces uterine vasoconstriction. The fetal circulation responds with bradycardia, decreased blood flow, and a fall in oxygen content. The effects of maternal hypocapnia on uterine blood flow are variable. Alkalosis, either metabolic or respiratory, may compromise fetal oxygenation, presumably by causing umbilical artery vasoconstriction as well as shifting the maternal oxyhemoglobin dissociation curve. Finally, positive intrathoracic pressures produced by the ventilator may also depress uterine blood flow.

Another major concern is that surgery and anesthesia may provoke abortion or preterm labor. Duncan et al. reported that patients undergoing surgery during the first or second trimester had twice the usual number of spontaneous abortions.

SPECIFIC SURGICAL PROBLEMS IN PREGNANCY

Appendicitis

Appendicitis is one of the most common surgical complications of pregnancy. The incidence is between 1/1,000 and 1/2,000, which is roughly equivalent to that in the nonpregnant population. Thus, pregnancy does not appear to be a causative factor.

During pregnancy, the cecum is displaced upward. In late pregnancy, the appendix may at times lie as high as the right costal margin but usually is located up to 3 cm above the iliac crest. As the infection becomes more severe and involves the local peritoneum, the pain becomes more constant and localized to the site of inflammation. Thus, during late pregnancy, appendicitis commonly presents as right-flank or upper-quadrant pain. However, adhesions may limit appendiceal displacement by the enlarging uterus and may result in pain in the lower abdomen or even in the lower flank. The onset of crampy pain is typically followed by anorexia, nausea and vomiting. Many of these constitutional symptoms may be misinterpreted as complaints typical of the pregnant state.

Early in the course, the temperature and pulse rate may be normal. Later, low-grade temperature elevations or even a normal temperature may be present. Due to abdominal wall distention and thinning of the muscles, detection of local muscle spasm or rigidity becomes more difficult as pregnancy progresses. The pain may be increased by fetal movement.

Treatment with antibiotics is not indicated in uncomplicated appendicitis. Prompt surgical therapy will minimize maternal and fetal morbidity by preventing progression to rupture and peritonitis. The choice of incision is a matter of personal preference. The patient’s right side can be slightly elevated to improve operative exposure and relieve the pressure of the uterus on the major vessels. Manipulation of the uterus should be kept to a minimum, if there is doubt as to the diagnosis, a midline incision should be used for better access to other viscera.

The effects on the fetus depend upon the severity of the disease. Fetal mortality is 9% when acute appendicitis is diagnosed and promptly treated, but rises to 36% in the presence of peritonitis. Maternal demise may also occur in the presence of peritonitis and overwhelming intra-abdominal sepsis.

Biliary Tract Disease

The incidence of biliary tract disease is between 1/1,000 and 1/2,000 pregnancies. Pregnancy is thought to be contributory to biliary tract disease because of its effects in altering gallbladder function. The high progesterone levels inhibit smooth muscle contractility and the gallbladder volume is increased to twice the nonpregnant size after the first trimester. The rate and degree of emptying are reduced. The high residual volume may promote cholesterol precipitation.

Biliary tract disease during pregnancy may range from intermittent attacks of biliary colic, to acute cholecystitis, choledocholithiasis and biliary pancreatitis. These patients present with symptoms similar to those of the nonpregnant state (i.e. nausea, vomiting and right upper quadrant or epigastric pain with tenderness). Undoubtedly, many mild attacks are overlooked because the complaints may be indistinguishable from those of normal pregnancy. About one-half of women with history of mild gallbladder attacks before pregnancy will develop severe attacks during gestation which require surgery.

Acute cholecystitis may initially be treated with similar conservative measures and antibiotics. However, failure to suppress the infection with such therapy may lead to necrosis or perforation of the gallbladder, with significant risk of maternal death. Therefore, in the absence of immediate improvement, surgery is indicated.

Peptic Ulcer Disease

The most common causes of upper GI bleeding in pregnancy are esophagitis and gastritis. Medical therapy is almost always successful. Peptic ulcer disease generally becomes quiescent as gastric acid levels fall during pregnancy. Thus, complications are distinctly unusual. Bleeding has been
occasionally reported, but can almost always be controlled
with endoscopy or, in rare cases, with transcatheter occlusion.
Perforation of an ulcer is associated with high maternal and
fetal mortality rates unless prompt surgery is undertaken.
Perforations present with the sudden onset of excruciating
abdominal pain, which may be accompanied by nausea and
vomiting. On examination, the patient demonstrates diffuse
abdominal tenderness and involuntary guarding if there is
free perforation into the abdominal cavity.

Suspected perforation of a viscus is an indication for
radiographic evaluation. An erect chest film or plain films
of the abdomen will show free air, more than 95% of the
time. This study should be done in spite of the concern
about radiation exposure to the fetus. Simple repair of the
perforation is the standard surgical treatment.

**Bowel Obstruction**

Fortunately, this condition is rare, occurring only once in every
3,000–6,000 pregnancies. Adhesions after prior operations,
particularly after appendectomy and pelvic surgery are the
most frequent cause. Colonic volvulus, mainly cecal, is the
second most common cause and is responsible for 25% of the
obstructions. Intussusceptions may also cause obstruction,
but is extremely rare.

Obstruction due to adhesions usually occurs during the
first pregnancy after abdominal surgery. Pregnancy may play
a role in that the enlarging uterus displaces the bowel. Existing
adhesions may limit motion and thus lead to obstruction.
Postpartum obstruction may result when the uterus rapidly
decreases in size and returns to the pelvis.

Patients with bowel obstruction present with an abrupt
onset of crampy abdominal pain associated with hyperactive
peristaltic rushes heard on auscultation. Since, the small
bowel and cecum are midgut structures, the pain is generally
perceived as periumbilical. The pain is accompanied by
nausea, vomiting and constipation. As time passes, the
peristalsis decreases and the abdomen finally become
silent. Abdominal distension may be marked, although this
can be difficult to appreciate in late pregnancy. The patient
may continue to pass flatus or stool which is distal to the
obstruction. This should not mislead the physician into
discarding the diagnosis of bowel obstruction. Intestinal
infarction may not be ascertainable until shock supervenes.
At this point, more than one-half of all patients go into pre
term labor. Suspected obstruction is one of the few abdominal
conditions in which X-rays are clearly indicated. With small-
bowel obstruction, the supine film classically shows dilated
small-bowel loops containing air which produce the familiar
“ladder” pattern of air/fluid levels on the upright film.

Prompt and adequate fluid resuscitation is essential.
Nasogastric tube decompression should be performed and
the patient prepared for surgery. Hill et al. reported an overall
mortality rate of 10%, primarily due to sepsis and shock, with
a 3.3–50% incidence of fetal demise.

**Intra-abdominal Hemorrhage**

There are many possible sources of intra-abdominal bleeding
during pregnancy. Pre-existing aneurysms may rupture
during pregnancy. In some cases, the bleeding seems to have
arisen spontaneously from normal vessels. In other cases,
there may be no history of antecedent injury, but the bleeding
may be related to the occurrence of a minor, unremembered
trauma. In cases of massive bleeding, diagnostic studies
are foregone and the source of bleeding is established
intraoperatively.

Toxemia of pregnancy or maternal hypertension are
frequent, underlying causes of rupture of the liver during
pregnancy. Toxemia results in necrosis at the periphery of
the hepatic lobules. The necrotic areas become confluent,
resulting in a subcapsular hematoma which proceeds to
rupture. Bleeding occurs late in pregnancy, particularly in
preeclamptic patients. These women may have complained
of chronic epigastric or right hypochondral pain. In addition
to surgical control of bleeding, termination of the pregnancy
often is needed to reverse the underlying pathologic changes.

The surgical treatment of hepatic hemorrhage must be
individualized. In some cases, ligation of bleeding vessels
or mattress suturing of the bleeding area may suffice. In
others, partial lobectomy may be required. External drainage
of the hepatic bed is generally indicated because of the risk
of continued oozing. Replacement of clotting factors and
platelets correct the consumptive coagulopathy associated
with massive hemorrhage.

Splenic artery aneurysms are another source of intra-
abdominal hemorrhage, generally during the third trimester
of pregnancy possibly, the mechanical stresses associated
with displacement or increased intra-abdominal pressure
lead to rupture of a pre-existent aneurysm already weakened
by the medial changes associated with pregnancy. Splenic
aneurysms are often multiple or accompanied by aneurysms
elsewhere in the visceral arteries.

Rupture of the spleen itself is a rare complication of
pregnancy and may appear to be spontaneous or result
from prior trauma, either recent or remote in time. Prompt
splenectomy is required to control the bleeding.

Uterine and ovarian vessels may also rupture, particularly
during labor. Suture ligation, hypogastric artery ligation or
even hysterectomy may be needed to control hemorrhage.

Unfortunately, the sources of hemorrhage described
above are associated with rapid egress of blood from the
maternal circulation. Maternal mortality is about 15%, while
fetal loss is up to 70% in these cases. In late pregnancy,
emergency cesarean section may be employed to save the life
of the fetus. Other complications of emergency surgery, such
as infection or consumptive coagulopathy, are common after these operations.

**Anal Pathology**

Pregnancy tends to exacerbate problematic hemorrhoids. Sitz baths often relieve the pain of sphincter spasm. Dietary fiber supplementation may aid in controlling constipation. Prolapsed hemorrhoids should be manually replaced after each bowel movement. Clots should be removed from thrombosed hemorrhoids if the patient is in severe pain. Intractable bleeding is rare. Thus, conservative management generally suffices until after delivery.

Anal fissures may occur during pregnancy and are characterized by pain exacerbated by bowel movements. They generally respond to conservative therapy directed against constipation. If anorectal abscesses occur they should be drained promptly. If the infection penetrates beyond the external sphincter, an ischiorectal abscess may develop with systemic sepsis. If drainage of the abscess leads to development of a chronically draining fistula, definitive surgery can be postponed until the postpartum period.

**Hernias**

The displacement of intestine caused by the gravid uterus tends to empty lower abdominal hernias of their contents. As pregnancy progresses, even umbilical and suprapubic hernias are found devoid of bowel contents because of the enlarging uterus. If a hernia is reducible, it may be observed and repaired after delivery. If a hernia is not reducible, one must consider the possibility that adhesions have fixed the contents to the sack. As pregnancy progresses, obstruction or strangulation may occur. Accordingly, repair should be considered early in pregnancy for irreducible hernias.

**Cervical Cancer**

The most frequently diagnosed neoplasm of pregnancy is cervical cancer, with an incidence of 1/1,200 pregnancies. The great majority occur in multiparous women and are squamous in cell type. If diagnosed in the first trimester, termination of the pregnancy should be strongly considered if invasive disease is to be cured. The fetus may be delivered in utero, if radical hysterectomy is indicated. Later in pregnancy, hysterectomy may be required before radiation therapy. If the pregnancy is advanced, consideration should be given to waiting for fetal viability, particularly if microinvasive carcinoma is found at biopsy. However, there are no guidelines, defining a safe waiting period. These cancers, regardless of cell type, are not hormonally responsive. Therefore, pregnancy seems to have no effect on the prognosis of cervical cancer.

**Breast Cancer**

Breast cancer is discovered in 1/3,000 pregnant women. Examination of the breasts, and therefore, early detection, is more difficult than in nonpregnant patients. In the post-partum period, continued engorgement due to lactation also makes detection difficult. Cytologic specimens may be difficult to interpret due to the pregnancy related cellular hyperplasia. Unfortunately, about 41% of the patients present with advanced disease and in very rare cases the fetoplacental unit may be involved. Even with the recent evidence in favor of limited resection and radiation, modified radical mastectomy and axillary node dissection should be considered to avoid fetal irradiation.

**Melanoma**

Melanomas account for 8% of the cancers associated with pregnancy. This is the most frequent cancer to metastasize to the placenta and then to the fetus. Yet this is an extremely rare event. Although melanocyte-stimulating hormone (MSH) is increased in pregnancy, the influence of pregnancy on malignant melanomas is uncertain, with some authors reporting progression and others no effect on the lesions. It is clear that some melanomas do have estrogen receptors. However, there are no documented survival differences between pregnant and nonpregnant patients with melanoma.

**Ovarian Cancer**

Ovarian cancer is a rare tumor, with an incidence of 1/20,000 pregnancies. Epithelial cell and germ cell tumors predominate. Detection relies upon physical examination in early pregnancy or upon ultrasound examination, later on. Fortunately, only 2–5% of ovarian masses in pregnant patients are malignant. Any mass greater than 5 cm in size, which is solid on ultrasound examination should be an indication for exploration, if it persists into the second trimester. Complications such as torsion, rupture, bowel obstruction, or development of ascites mandate intervention. If a neoplasm is found, exploration of the contralateral ovary and staging by omentectomy, examination of the retro-peritoneum, and sampling of enlarged lymph nodes is necessary. Alkylating agents are often used for chemotherapy because of their lesser effect on the fetus.

**Hematologic Malignancies**

Although, leukemia is very rare in pregnancy, lymphoma is not. The incidence of lymphoma is 1/1,000–1/6,000 pregnancies, and after melanoma it is the most common neoplasm to involve the fetoplacental unit. Roughly, one-third of cases are Hodgkin’s disease. Staging laparotomy is generally...
Emergency in Pregnancy

not required for non-Hodgkin’s lymphomas, and in fact is not usually required even for Hodgkin’s disease. Therapy must be individualized. Early in pregnancy, particularly in advanced disease, termination of the pregnancy may be considered to allow effective therapy. Combination chemotherapy is generally required for non-Hodgkin’s lymphoma and poses significant risks to the fetus. For Hodgkin’s disease, radiation may be the treatment of choice for disease above the diaphragm. However, mantle-field radiation, even with shielding, may pose unacceptable risks to the fetus. Otherwise, chemotherapy is indicated. Occasionally, vinblastine, which seems to have minimal fetal effects, is used as a temporary measure while awaiting fetal maturity.

The diagnosis of cancer during pregnancy is an extremely traumatic event. Each patient deserves an individualized treatment plan after assessing the likely effects of therapy or its delay on the fetus and the mother. Many recent reviews of cancer during pregnancy, provide data upon which suitable recommendations can be made.

Neurosurgical Conditions

Spontaneous subarachnoid hemorrhage, is the most common cerebrovascular catastrophe associated with pregnancy. The initial symptoms are sudden headache, nausea, vomiting and nuchal rigidity, which can be followed by seizures or local neurologic deficits. Aneurysmal rupture occurs in approximately, 1/2,000–1/10,000 pregnancies and carries a mortality of more than 25%. Cerebral bleeding is frequent enough to account for 5–25% of all maternal deaths. About 5% of the population have unruptured intracranial aneurysms. Most authors feel that pregnancy appears to have little or no effect on the incidence of rupture. Aneurysms are more frequent in the anterior portion of the circle of Willis, and are multiple in 20% of patients. They are congenital, and rupture may be precipitated by hemodynamic changes. In pregnancy, ruptures cluster in the 3rd trimester. Arteriovenous malformations account for an equal number of subarachnoid hemorrhages. Bleeding occurs in a random fashion throughout pregnancy. They occasionally may occur in the spinal cord rather than the brain.

Angiography, usually demonstrates the structural abnormality causing the bleeding. Treatment must be individualized. Some patients may require surgery before delivery. Therapeutic embolization may be successful in preventing further bleeding. In patients with known, un-corrected aneurysm, labor does not appear to increase the incidence of rupture. Yet cesarean section, may be appropriate if the patient recently bled and there was no surgical correction. Even then, successful spontaneous vaginal delivery has been reported.

Pregnancy seems to increase cerebral edema in patients with neoplasms of the brain. Decisions about therapy and continuation of the pregnancy must be individualized depending upon the length of pregnancy, the symptoms, the type of tumor, and the expected prognosis. Pituitary adenomas often enlarge and sometimes cause neurological symptoms. Magyar and Marshall reported that 25% of their patients complained of headaches or developed visual disturbances during pregnancy. Thirty percent of these patients required surgical intervention or radiotherapy during pregnancy. If the tumor size remains stable throughout pregnancy or causes minimal symptoms, it will frequently regress in the postpartum period.

Cardiac Surgery

There is an increased incidence of prematurity and intrauterine growth retardation with uncorrected cyanotic congenital heart disease. Almost all types of cardiac surgery have been carried out during pregnancy, often using cardiopulmonary bypass. Two of the most common surgical problems are the existence of abnormal or prosthetic valves, and pregnancy in a patient at risk of aortic rupture.

Among the many hemodynamic derangements associated with maternal heart disease, pulmonary hypertension is the most dangerous. It is associated with a maternal mortality of 30–50%. Pregnancy should be avoided or interrupted. In particular, mitral stenosis from rheumatic heart disease is a common valvular defect. Twenty-five percent of women with pre-existing mitral stenosis develop pulmonary edema during pregnancy. The cardiac output is fixed in these women. If they require general or obstetric surgery during pregnancy, they can be managed with appropriate support of ventricular preload. If medical management of mitral stenosis is ineffective, percutaneous or closed valvulotomy can be performed with the same operative risk as in nonpregnant women. If this is not possible, valve replacement can be undertaken. Fetal loss occurs in 10–20% of these patients.

During pregnancy, reported complications of prosthetic valves include thromboembolism despite anticoagulants, red cell and platelet destruction by the prostheses, hemorrhage due to excessive anticoagulation, and bacterial endocarditis. Cardiac function may deteriorate, or the prosthetic valves may not function well or may even clot. Careful follow-up during gestation may minimize these complications. Cardiac surgery, if required, should be done before the third trimester, if possible.

Among the congenital lesions, surgery for coarctation of the aorta is the most important. Because of degeneration in the aortic media, ruptures may occur due to the hemodynamic changes of pregnancy. In patients who have not undergone correction prior to pregnancy, maternal mortality has been reported to be 3.5% due to rupture, congestive heart failure, endocarditic, or central nervous system (CNS) bleeding. Therefore, a newly discovered coarctation of the aorta during pregnancy should probably be repaired.

Marjan’s syndrome predisposes women to rupture of the aortic root. In fact, 50% of the aortic ruptures occur during pregnancy. Minimal cardiac involvement generally indicates
a safe clinical course during pregnancy. The risk of rupture is directly related to abnormalities of the aortic valve and a root diameter greater than 40 mm.

**TRAUMATIC INJURIES DURING PREGNANCY**

**Blunt Trauma**

Trauma is the leading nonobstetric cause of maternal mortality, accounting for 20% of maternal deaths. Minor injuries frequently occur, and do not seem to lead to fetal loss. Fetal demise from major blunt trauma increase from 8.8% in the first trimester, to 40–50% during the second and third trimesters.

Blunt trauma may result from rupture of the membranes and in preterm labor. In more serious injuries, the gravid uterus may be ruptured. Rupture of the uterus commonly occurs at the third trimester, but is rare before the second trimester. Occasionally, blunt trauma may result in fetal injury, particularly when the pelvis and lower abdomen receive large impact forces. Diagnosis of intrauterine fetal injury may be difficult. Fetal skull fractures and neurologic trauma are the most frequent findings at autopsy or at birth. Placental abruption is the most frequent cause of fetal demise when the maternal injuries are not lethal. The separation may manifest at the time of injury or later, with the great majority of them in the first 24 hours. For this reason, even seemingly moderate blunt trauma should be considered as an indication for fetal heart rate monitoring and observation for 24–72 hours. Placental abruption is the most common cause of acute disseminated intravascular coagulation after trauma.

In addition to placental separation, the fetal surface of the placenta may tear and lead to fetal hemorrhage. The fetal distress which results can be detected by fetal heart rate monitoring.

**Penetrating Trauma**

Damage to the uterus from penetrating trauma increases in frequency, as pregnancy progresses and is associated with a high fetal mortality rate. However, it is possible for the fetus to survive minor intrauterine injuries. Interestingly, intrauterine healing differs from that in the neonate. In early pregnancy, there is local mesenchymal proliferation without repair of the exposed tissues. There is no capillary proliferation, leukocyte infiltration, or formation of granulation tissue. After the 20th week of gestation, healing mechanisms become more like those in the neonate, except that wounds heal slowly. While penetrating injuries to the upper abdomen may cause damage to maternal intra-abdominal organs. Franger et al. recommended conservative management of gunshot injuries if:

- The mother is hemodynamically stable
- The entrance wound is below the uterine fundus
- There is no evidence of blood in the GI or urinary tracts
- The bullet can be demonstrated within the uterus.

This management scheme is even more applicable to knife injuries and parallels the development of conservative management of stab wounds in nonpregnant patients.
Critical Care in Obstetrics: An Overview

INTRODUCTION

Critical care or intensive care includes monitoring and definitive therapy of patients with acute but reversible life-threatening illnesses or injuries, and is reserved for patients with potential or established one or more multiple organ system failure (MOSF). The purpose of the intensive care units (ICUs) is to ensure timely and rapid intensive care that cannot be provided in general wards. Since the past 2 decades the importance of critical care in obstetric patients has been realized; however, there are few reports in the international literature of obstetric ICUs (OICUs), and most of the hospitals treat the critically ill obstetric patients in the general ICU (GICU) or the medical/surgical ICU. This is probably because critical care is expensive and the developing countries with high maternal mortality ratios (MMR), who actually need these OICUs, probably do not have adequate resources to establish them.

The MMR in India is 3 per 1,000 livebirths. The major causes of maternal death in India are hemorrhage (38%), sepsis (11%), abortion (8%), hypertensive disorders (5%), obstructed labor (5%) and other conditions (34%). Anemia and viral hepatitis are important indirect causes of maternal deaths in India. Preventive medicine can avert majority of these deaths; however, timely institution of critical care is important to prevent a significant number of these deaths.

Civetta has described three groups of patients for ICU care:
- Physiologically stable patients who need intensive observation
- Physiologically stable patients who need extensive nursing care and monitoring (frequently of an invasive nature)
- Physiologically unstable patients who require constant nursing and physician care.

Critically ill obstetric patients requiring admission to an ICU include those with:
- Hemorrhagic shock
- Septic shock
- Eclampsia and complicated preeclampsia
- Severe anemia with cardiac failure or pregnancy-induced hypertension (PIH) or sepsis or in labor
- New York Heart Association (NYHA) classes III and IV cardiac disease, especially those with PIH, anemia, or in labor
- Hepatitis with coagulation failure, encephalopathy or oliguria
- Disseminated intravascular coagulation
- Diabetic ketoacidosis
- Acute pulmonary injury and respiratory failure
- Severe hyperthyroidism.

The majority of reports state that hemorrhage, hypertensive disorders of pregnancy and sepsis are the main indications for admission to the ICU.

COSTS OF INTENSIVE CARE

Intensive care is expensive and the costs should be considered at the microeconomic and macroeconomic levels.
- Microeconomic cost is the cost of managing one patient in an ICU at the hospital level, and varies with the diagnosis and severity of illness. The cost in a tertiary ICU in India (1991) was reported to be ₹3,200 per day, but is now probably around ₹15,000 per day. In the USA although ICUs account for only 5% of all hospital beds, the cost of
care for these patients is approximately 20–28% of total hospital costs.¹³

- Macroeconomic cost is the cost of ICUs at the national or regional level. This is 0.2% of gross national product (GNP) in Canada and 0.8% of GNP in the USA.¹⁴ Data for India are not available.

To rationalize services and optimize resource utilization, health policies should ensure cost-effectiveness of an OICU. A prospective needs evaluation should be undertaken and there should be a demonstrated need for the proposed service. A hospital that caters to a small number of booked cases may not require an OICU; in such hospitals, special cubicles can be made to deliver these women in the GICU. In contrast, a tertiary or large government run hospital that caters to a large number of unbooked cases reporting in advanced pregnancy or in labor (majority from the low socioeconomic strata) would benefit from an OICU.

Reports in the literature have stated that the utilization rate of the ICU to range from 0.11% to 0.89% of all deliveries,¹²,⁶-¹¹ with majority reporting a rate of 0.2% of all deliveries.⁷,⁸,¹⁵,¹⁶ The maternal mortality amongst obstetric patients admitted to the ICUs is reported to vary from 3.3%³,¹⁷ to 28%;⁷ this probably reflects the differences between the patient populations.

It is important to emphasize that the recommended standards for an ICU should include the— in terms of space, staff and equipment; otherwise, the very purpose of the ICU will be defeated. I have described details regarding the organization of an OICU earlier.³

**NEED FOR AN OBSTETRIC ICU**

Care of the critically ill pregnant woman is a challenge to the clinician as these patients represent a potential mortality of 200% (mother and fetus). The patient’s disease and the therapy affect two individuals with vastly differing physiologies. The pregnant woman undergoes dramatic physiologic and physical changes that have to be borne in mind when instituting critical care. With improvement in antenatal care the number of ICU admissions for obstetric cases would decline in developing countries; however, this trend may be offset by the rising trend of increasing maternal age and pregnancies in women with complicated chronic medical disorders.

**INVESTIGATIONS TO BE DONE IN THE CRITICALLY ILL OBSTETRIC PATIENT**

These include those that can establish or rule out organ system failure (OSF) and those that are specific for the particular case. Tests for fetal viability and monitoring (after 30 weeks of gestation) should be performed when indicated. Various imaging studies including X-rays should be performed when indicated, keeping the exposure to ionizing radiation to the minimum and using a lead shield for the abdomen, whenever possible. These are listed in Table 1.

The frequency of testing will depend upon the condition of the patient.

**FACTORS AFFECTING OUTCOME OF CRITICAL ILLNESS**

The outcome of any illness depends upon the following patient factors—age, the specific disease and its severity, physiologic reserve and the response to therapy. Chronic diseases decrease the physiologic reserve. The type, timing and amount of therapy also determine the outcome. The key to success in the treatment of critically ill patients is the timely recognition of the need for intensive care and to administer it immediately by qualified personnel. The obstetric and anesthesiology staff has an important role to play in triaging women for intensive care. Obstetric patients at the extremes of the reproductive age (< 18 years and > 40 years) are at an increased risk for a poor outcome because of the associated social problems (unmarried pregnant teenagers and multiparous women with chronic diseases undergoing illegal abortion).

**ILLNESS SEVERITY SCORING SYSTEMS**

Prognostic stratification can help in determining the need for admission to the OICU and treatment decisions. Several scoring systems have emerged over the recent years to stratify severity of illness, and help in predicting outcome of illness.

Abbreviations: PT, prothrombin time; aPTT, activated partial thromboplastin time; AST, aspartate aminotransferase; ALT, alanine aminotransferase; ALP, alkaline phosphatase; HCO₃, bicarbonate; PaO₂, partial pressure of oxygen in arterial blood; PaCO₂, partial pressure of carbon dioxide in arterial blood; ECG, electrocardiogram; FDP, fibrin degradation products; NST, nonstress test; CAT, computed axial tomography
Emergency in Pregnancy

There are a few reports on the use of these scoring systems in pregnant women; the Acute Physiology and Chronic Health Evaluation II (APACHE II) score, has been evaluated maximally. Except for the study by El-Solh and Grant all other reports have shown that the actual mortality rate is lower than the predicted rate. Bhagwanjee et al. have shown that the Glasgow Coma Scale score reflects outcome in eclampsia cases better than the APACHE II score.

**MULTIPLE ORGAN SYSTEM FAILURE**

Knaus and colleagues defined OSF in 1985 and a modification by Rutledge and Sibbald is depicted in Table 2. Increased mortality rates are associated with an increase in the number and duration of OSFs. After only 24 hours, mortality in patients with three or more OSFs is reported to be 90%. Prompt recognition and treatment of patients with potential or established OSF can help in improving survival.

**INVASIVE HEMODYNAMIC MONITORING IN THE CRITICALLY ILL OBSTETRIC PATIENT**

This is seldom required. Indications for invasive monitoring include refractory or unexplained hypotension, oliguria, pulmonary edema and cardiac failure, selected cases of massive blood loss or replacement, acute respiratory distress syndrome (ARDS), amniotic fluid embolism and NYHA classes III and IV cardiac disease in labor or undergoing major surgery.

Invasive monitoring is usually performed through the external or internal jugular vein or the subclavian vein. The femoral and antecubital veins are used less frequently because of difficulty in positioning the catheter. The antecubital vein is preferred in the woman with a coagulopathy.

*Glasgow Coma Scale Score: Sum of best eye opening, best verbal and best motor responses. Scoring of responses are as follows:

- **Eye open:** Spontaneously (4), to verbal command (3), to pain (2), no response (1)
- **Motor:** Obeys verbal command (6), response to painful stimuli, localizes pain (5), flexion-withdrawal (4), decorticating rigidity (3), decerebrate rigidity (2), no response (1)
- **Verbal:** Oriented and converses (5), disoriented and converses (4), inappropriate words (3), incomprehensible sounds (2), no response (1)
- If intubated, use clinical judgment for verbal responses as follows: Patient generally unresponsive (1), patient’s ability to converse in question (3), patient appears able to converse (5).

Abbreviations: bpm, beats/minute; PaCO₂, partial pressure of carbon dioxide in arterial blood; A-a, alveolar-arterial oxygen gradient; DO₂, oxygen delivery; CPAP, continuous positive pressure airway pressure; PT, prothrombin time; DIC, disseminated intravascular coagulopathy; AST, aspartate aminotransferase
Complications of Venous Lines for Invasive Monitoring

- Misinterpretation or overinterpretation
- Pneumothorax—complicates 5% of subclavian and 0.01% of internal jugular vein insertions
- Lethal intrathoracic bleeding during subclavian vein cannulation, with injury to either arteries or veins
- Ventricular and supraventricular arrhythmias can occur during passage of the pulmonary artery catheter as it passes through the right side of the heart
- Massive hemorrhage can occur when the catheter or its introducer get disconnected from the intravenous (IV) lines
- Rare complications include pulmonary artery rupture, pulmonary infarction, sepsis, knotting of catheter, thromboembolism and balloon rupture

It is estimated that invasive monitoring is associated with major complications, including death, in 3% of patients.

Arterial Lines in Critically Ill Patients

These allow continuous monitoring of systemic blood pressure as well as allow easy access for arterial blood gas analysis.

Complications of Arterial Lines

- Sepsis
- Hematoma
- Vessel thrombosis
- Serious complications of gangrene and loss of digit or extremity occur in less than 1% of patients.

Hemorrhage, sepsis and hypertensive disorders are important causes of maternal mortality and morbidity in India. Majority is associated with the lethal ARDS. A few points should be remembered with regard to the management of these conditions.

HYPERTENSIVE DISORDERS OF PREGNANCY

Severe cases of preeclampsia aim at lowering the blood pressure to 130/90 mm Hg, but not lower than this. IV drip of nitroglycerine should be started if the diastolic blood pressure is persistently above 120 mm Hg; this should be monitored by continuous electronic measurement (noninvasive) of the blood pressure. It is important to maintain an hourly urine output at 30 mL/hour in order to detect and treat oliguria at the earliest. IV fluids should be administered judiciously to avoid iatrogenic pulmonary edema. In the comatose patient, not responding satisfactorily to drugs, aimed at treating cerebral edema, fundoscopy should be repeated and a computed axial tomography (CAT) scan of the brain is essential. The Hemolysis, Elevated Liver enzymes, Low Platelet count (HELLP) syndrome and disseminated intravascular coagulopathy (DIC) should be diagnosed and treated early; "smoky" urine is often an indicator of a coagulopathy. Fresh whole blood, fresh frozen plasma (FFP) and platelet concentrates should be readily available when such patients are admitted in the ICU.

SEPSIS

Peritonitis due to puerperal sepsis and illegal abortion, and chorioamnionitis are frequently encountered in the obstetric population. These women are at very high risk of progressing to septicemic shock and ARDS. Early drainage of the pus, evacuation of infected uterine contents, termination of pregnancy by Cesarean section, or even hysterectomy in some cases are the mainstay of treatment. Broad-spectrum antibiotics that cover aerobic and anaerobic infections should be started in appropriate dosages. Patients will benefit from IV steroids for the prevention of septicemic shock. Maintaining good tissue perfusion and tissue oxygenation are crucial for the prevention of complications. Hemoglobin level should be maintained above 8.5 g/dL and coagulopathy should be diagnosed and treated at the earliest.

OBSTETRIC HEMORRHAGE

Hemorrhage is common in obstetrics. Blood loss is often underestimated by 30–50%. Patients suffering from antepartum hemorrhage (APH) are at high-risk for postpartum hemorrhage (PPH) and the two frequently occur in the same patient. Conservative treatment in APH should not be unduly prolonged—one can lose the mother as well as the...
fetus. Frequent recurrent bouts of bleeding in a woman who is anemic and undernourished is an indication to terminate the pregnancy irrespective of the period of gestation, because this patient does not have a good physiologic reserve to compensate for a massive bout of hemorrhage. Similarly, conservative measures to treat PPH should not be prolonged. Hysterectomy is lifesaving in cases of intractable PPH, but may not be so if performed too late.

It is important to recognize simple signs that can provide a clue to the severity of blood loss. Table 4 has been developed for the management of trauma patients, and can be applied to the obstetric patients as well.29

In acute hemorrhage, the immediate hematocrit may not reflect the actual blood loss till after 4 hours or more than 32 hours. However, with rapid infusion of crystalloids, more rapid equilibration occurs. The hourly urine output is one of the most important parameters to monitor in the hemorrhaging patient. In the absence of diuretics, the rate of urine output reflects the adequacy of renal perfusion, and in turn, the perfusion of other vital organs because renal blood flow is especially sensitive to blood volume changes. The urine output should be maintained at least at 30 mL/hour, and preferably at 1 mL/kg/hour. If the urine output is not satisfactory despite adequate volume replacement, dopamine should be infused at the dosage of 2 μg/kg/min.

Treatment begins with controlling the hemorrhage and prompt restitution of the blood volume. Crystalloids are used for initial volume replacement and 3 mL of fluid is used to replace 1 mL of estimated blood loss. Crystalloids are better than colloids for resuscitating the bleeding patient.30 Blood transfusion should aim at maintaining the hematocrit above 25% or a hemoglobin above 8 g/dL. Whole blood (preferably fresh) is ideal for the woman with acute blood loss.

In patients with massive blood loss31 FFP and platelet concentrates will be required, if enough fresh blood is not available, to avoid dilutional coagulopathy. Requisitions for these should be made well in advance to avoid delay. In these women, it may be prudent to transfuse screened and typed blood rather than cross-matched blood, as the former is readily available in lifesaving circumstances. Temperature controlled warmers for the fluid and blood (to 37°C) should be available, otherwise hypothermia will ensue.

Women suffering from hemorrhagic shock develop metabolic acidosis and hypothermia as a result of massive transfusion; these result in and exacerbate preexisting DIC. These women also are at high-risk for renal failure and ARDS, and these should be prevented by appropriate management including adequate volume replacement, maintaining the hematocrit above 25%, adequate oxygenation (which may require elective mechanical ventilation) and timely use of dopamine infusion.

Facility for autologous blood transfusion intraoperatively by using the cell-saver should be available in referral hospitals. The use of the military anti-shock trousers (MASTs) should be popularized in obstetrics, especially when the patient is being transferred to a higher center or is undergoing resuscitation before definitive surgery. The MASTs stop almost all bleeding (even arterial) below the renal arteries even in the presence of coagulopathy.32 They can be applied within 3 minutes with the patient in the bed or on the or table after a Foley catheter has been inserted. Usually a pressure of 25–35 mm Hg is sufficient and this can be maintained for 4–8 hours (up to 24 hours).

### ACUTE RESPIRATORY DISTRESS SYNDROME

This is the worst form of respiratory failure, and has a mortality of 40–50% in nonpregnant patients and can be as high as 90% if it was triggered by sepsis.2 Perry and colleagues33 reported a maternal mortality of 25%. Delivery does not improve maternal oxygenation.34 Timely recognition of the conditions that cause this condition, diagnosis in the early stage and prompt institution of appropriate therapy is crucial for lowering the mortality and morbidity due to ARDS. Infection, hemorrhage, preeclampsia and eclampsia are common causes of ARDS in pregnant women. Perry and colleagues noted that more than 70% of women with ARDS have a combination of sepsis, shock, trauma and fluid overload.33

Acute respiratory distress syndrome is a pathophysiological diagnosis, and includes pulmonary alveolar injury sustained via the airways and endothelial injury sustained via the pulmonary vasculature. Chemokines recruit the neutrophils to the site of inflammation; the neutrophils secrete cytokines and initiate tissue injury. This results in increased capillary permeability, loss of lung volume and shunting with arterial hypoxemia.2

SECTION 3

36.6% of were methicillin-resistant following resistance rates: 80.8% of all Infection Control Consortium (INICC) ICUs showed the
aggregated data from all International Nosocomial Infections in the ICU

device-associated nosocomial infections in the ICU

These pose a great threat to patient safety, especially in developing countries. Rosenthal et al. reviewed these infections in 55 ICUs of eight developing countries (including India) and reported that 14.7% of patients were infected by these devices. The crude mortality for these infected patients ranged from 35.2% (for central venous catheter-associated bloodstream infections) to 44.9% (for ventilator-associated pneumonia). This report emphasizes the need for active infection control programs with proper surveillance of infection and treatment guidelines for every ICU.

Aggregated data from all International Nosocomial Infection Control Consortium (INICC) ICUs showed the following resistance rates: 80.8% of all Staphylococcus aureus were methicillin-resistant Staphylococcus aureus (MRSA), 36.6% of Pseudomonas spp. resistant to imipenem, 52.4% resistant to ciprofloxacin/ofloxacin, 56.8% Enterobacter spp. resistant to ceftazidime and 68.2% of Klebsiella spp. were resistant to ceftazidime.

THE NEED FOR AN ICU AT THE SUBDISTRICT AND DISTRICT HOSPITALS

A level I ICU with facility for short-term ventilation and 24 hours blood bank facility will go a long way in decreasing maternal mortality in India. Telemedicine can be utilized to provide continuous intensivist care to remote areas. The MAST suit should be recommended for the resuscitation of critically obstetric patients who are suffering from hemorrhagic shock.

CONCLUSION

There is a need for establishing obstetric ICUs in India, especially in the government-run hospitals catering to a large number of unbooked women from the low socioeconomic group. The obstetrician can play a vital role in the successful treatment of the critically ill obstetric patients by the timely recognition of the need for intensive care and ensuring that it is instituted immediately. Aggressive management of life-threatening complications is essential. The key to success is ensuring adequate tissue oxygenation by maintaining cardiac output, maintaining the hematocrit above 25%, and at times, mechanical ventilation.

REFERENCES

Emergency Obstetric Care for Reducing Maternal Mortality

Introduction

Maternal mortality continues to be a burning issue worldwide. Almost 600,000 women in the world die each year from pregnancy-related complications. Fifteen percent of all pregnant women develop life-threatening complications. The problem is more acute in developing countries leading to disability and death amongst women of reproductive years. Twenty percent of global maternal deaths occur in India. Besides every maternal death, there are twenty women who suffer severe morbidity so that their lives are not worth living. Since 70% of India’s population lives in rural areas, there is very high maternal mortality rate (MMR) in these settings due to lack of prompt and adequate treatment. Many programs have been instituted for identifying high-risk pregnancies by antenatal screening to try and address this major problem. Though useful, these efforts have not succeeded in reducing maternal deaths. This is because complications can develop in each and every pregnant patient (high-risk as well as low-risk). As a matter of statistical fact, majority of maternal mortalities are in low-risk patients and hence basic obstetric care must be made available at the grass root levels to all parturient women. Once an unpredictable complication occurs, she will require emergency services. Hence, to make a difference in saving women’s lives quality emergency obstetric care (EmOC) services are required to save a woman who develops life-threatening complications. Quality EmOC poses unusual challenge because EmOC must be available 24 hours a day, 7 days a week to be maximally effective. This is the only way in which we can help in reducing the MMR. Government of India has supported The Federation of Obstetric and Gynaecological Societies of India (FOGSI)/Indian College of Obstetricians and Gynaecologists (ICOGs) efforts of setting up EmOC training centers. This will help in making many first referral centers and district hospitals competent in providing emergency obstetric care. Hopefully, this public private partnership will help to reduce maternal mortality in India. Comprehensive EmOC certificate program has been implemented in 20 states of India.

Maternal Mortality: A Burning Issue Worldwide

Thirteen countries across Africa and South East Asia account for 67% of all maternal deaths. India tops the list. A million or more children are left motherless each year as a result of maternal deaths. Almost half (about 8 million) of perinatal deaths per year results from poor maternal health and inadequate delivery care.

India contributes nearly 47% of maternal death 253,000 deaths per year. One death in every 2 minutes, yet maternal mortality does not make headlines. Dr Fattalah, past president of International Federation of Gynecology and Obstetrics (FIGO) had rightly said that “women are dying because societies have yet to decide whether their lives are worth saving”.

Indian Scenario

India has an unacceptably high maternal mortality ratio of 200/100,000 livebirths as updated by CIA World Fact Book (2010). Twenty percent of Global maternal deaths occur in
India. Besides for every maternal death, there are twenty women who suffer severe morbidity so that their lives are not worth living. These women suffer from long-term disability such as chronic pain, vesicovaginal or rectovaginal fistula, impaired mobility and damage to reproductive system leading to infertility or prolapse of uterus. 70% of India’s population lives in rural areas where MMR is high due to lack of prompt and adequate treatment.

CAUSES OF MATERNAL DEATHS (FIG. 1)

Direct Causes (Fig. 2)

Hemorrhage (postpartum or antepartum) sepsis, complications of unsafe abortion, prolonged or obstructed labor, and hypertensive disorders of pregnancy, especially eclampsia are some of the complications, which can occur at any time during pregnancy and labor and without any forewarning.

These maternal deaths are preventable by evidence-based intervention. A swift and competent EmOC using resources effectively can have a significant impact on pregnancy outcome.

Other Problems that Contribute for Increased Maternal Mortality in India

Maternal mortality is not merely a health disadvantage but also a reflection of social and gender injustice. The low social and economic status of girls and women limits their access to education, appropriate nutrition as well as health and family planning services. All this directly impacts pregnancy outcomes. The overriding causes of high mortality in India are poor access to EmOC in case of a complication and absence of skilled birth attendant at delivery. Any skilled birth attendant also needs the backup of a functioning health system, i.e. having minimal infrastructure for managing life-threatening complications in pregnancy and labor like-availability of life saving drugs, safe blood, functioning operation theater with electricity, running water and anesthetist and 24 hours emergency obstetric care. These infrastructures are lacking in many small towns and villages of India.

KEY STRATEGIES TO SAVE LIFE OF PREGNANT WOMEN

- Skilled birth attendant at delivery
- Emergency obstetric care
- Timely and effective referral system
- Availability of safe abortion services.

WHY FOCUS ON EMERGENCY OBSTETRIC CARE?

Over the past several decades, maternal health programs have used antenatal screening to try to identify women at risk for complications. Though useful these efforts have not succeeded in reducing maternal deaths. It is proved by many studies that many women who develop complications do not have any known risk factors. Once an unpredictable complication occurs, she will require emergency services. As a result, 24 hours, quality EmOC services will be required to save a woman who develops life threatening complications.

There are three types of delays that can affect a woman’s chance of surviving an obstetric emergency.

1. Delay in problem recognition and decision making.
2. Delay in reaching a health facility.
3. Delay in receiving care at health care facility.

The last delay can be prevented by having a quality 24 hours EmOC services.

PUBLIC HEALTH CONCEPT

We have undertaken various public health intervention programs to reduce MMR for last 50 years (Fig. 3). Unfortunately
they have not yielded desired results. The emerging Public
Health evidences in the field of Reduction of MMR tell us a
different story. With the exceptions of prevention of anemia,
tetanus vaccination, universal availability of safe abortion
services and of course high quality family planning servic-
es, none, training of traditional birth attendants, high-risk
screening, can significantly reduce MMR. The public health
studies have clearly demonstrated that:
• Most critical complications occur amongst low-risk
  patients.
• They cannot be predicted or prevented effectively.
• They have to be managed effectively in time.

The management of critical complications need high
quality, accessible and timely interventions.
• This forms the basis of EmOC.
• It is proved by various studies that organization of such
  EmOC proves the cheapest (cost-benefit factor) to the
  administration with reference to the estimated maternal
death prevented (Fig. 4).

We have the greatest challenge to accomplish this
intervention successfully. If we analyze the components of
this intervention, we find that major deficit is in the sector of
human resources in the form of available qualified/trained
personnel to provide high quality comprehensive emergency
obstetric care.

Health Information of India 1999 (Table 1)

Present Need
6000 doctors competent in providing comprehensive
EmOC are required to make 2,000 first referral units (FRUs)
functional for 24 hours.
• Only 771 specialists of obstetrics and gynecology
  (Obs-Gyn)
• 25,506 medical officers (MO) in primary health center
  (PHC)
• Only 42% of days, obs-gyn services are available.
Emergency Obstetric Care for Reducing Maternal Mortality

433

Present Status

Now if we wait for all community health centers (CHCs) and FRUs to be equipped with qualified specialist obstetricians, years would sail by. As against this challenge, we have the strength to huge pool of Medical Officers (MBBS) with us.

It sounds absolutely rational that this strength should be utilized to provide Quality EmOC by training them in the skill of EmOC.

DEFINING EMERGENCY OBSTETRIC CARE

Emergency obstetric care is often discussed in terms of basic and comprehensive care that is provided to a woman with obstetric complications.

Basic Emergency Obstetric Care

In basic, EmOC facility, skilled birth attendant should be able to administer parenteral antibiotics, parenteral oxytocic drugs, parenteral anticonvulsants for pre-eclampsia and eclampsia, perform manual removal of placenta, perform manual removal of retained products, manual vacuum aspiration and perform assisted vaginal delivery.

Comprehensive Emergency Obstetric Care

In comprehensive EmOC, the doctors on duty should be able to perform all the functions of basic EmOC and in addition, he should be able to perform emergency cesarean section to save the life of woman. The facility of safe blood and anesthetist should also be available in centers having comprehensive EmOC services.

Challenges in Addressing Emergency Obstetric Care in Low Resource Settings

There is lack of standard guidelines in training doctors and their supervision. There is shortage of continuous supply of drugs and repair of equipment in time. Besides, there is lack of technical and clinical decision making skills. There is no emergency preparedness. Infection preventive practices are poor and not enough training facilities nontrainers are available to train nonskilled MBBS doctors in emergency obstetric care.

Quality EmOC poses unusual challenge because EmOC must be available 24 hours a day and 7 days a week to be maximally effective. Therefore, a locum doctor must be available and constant efforts must be made to make all the emergency drugs available all the time.

FEDERATION OF OBSTETRIC AND GYNAECOLOGICAL SOCIETIES OF INDIA AND EmOC

Emergency obstetric care is an emerging concept of rural obstetrician to reduce maternal mortality and FOGSI is committed to working toward a significant reduction in MMR in the near future by addressing this issue.

The concept of rural obstetrics has developed during the past few years all over the world. The aim is to make basic obstetric lifesaving surgery within limited resources accessible to those who have no access to it under existing socioeconomic circumstances.

Current curricula of most medical colleges are generated toward hospital oriented medicine and cater to urban population while population living in rural areas is being catered by nonspecialized doctors. Most of skilled obstetricians prefer working in urban areas.

This leads to situations to take action to ensure training enough number of human resources/staff providing EmOC in rural India. This should be the key strategy to reduce maternal mortality.

Federation of Obstetric and Gynaecological Societies of India is an association with more than 22,000 members. The aims of federation being to provide knowledge amongst its members; have fellowship and give services to improve reproductive health care of Indian women. FOGSI and its academic wing, ICOG have commenced a certification course in EmOC to develop skilled personnel to reduce maternal mortality in rural areas. This is competency based course of 16 weeks in comprehensive EmOC and 3 weeks course in updating knowledge of those doctors working in rural areas with not sufficient skills in EmOC. With 700 public sector obstetricians and more than 20,000 public sector nonspecialized medical officers in rural areas, the vision of the project is massive. FOGSI aims to establish high quality training centers in each state of India to train rural non-specialized doctors in comprehensive EmOC.

Government of India has supported FOGSI/ICOGs efforts of setting up EmOC training centers. This will help in making many first referral centers and district hospitals competent in providing emergency obstetric care. Hopefully,
SUMMARY OF KEY POINTS

- Almost 600,000 women in the world die each year from pregnancy-related complications. Fifteen percent of all pregnant women develop life-threatening complications.
- The problem is more acute in developing countries leading to disability and death amongst women of reproductive years.
- Twenty percent of Global maternal deaths occur in India. Besides for every maternal death, there are twenty women who suffer severe morbidity so that their lives are not worth living.
- Seventy percent of India’s population lives in rural areas where MMR is high due to lack of prompt and adequate treatment. India has an unacceptably high maternal mortality ratio of 4–5 per 1,000 livebirths (SRS 1998)
- Maternal mortality is not merely a health disadvantage but also a reflection of social and gender injustice.
- The overriding causes of high mortality in India are poor access to EmOC in case of a complication and absence of skilled birth attendant at delivery also, inadequate backup of having minimal infrastructure for managing life-threatening complications in pregnancy and labor.

Key strategies to save the life of pregnant women are:
- Skilled birth attendants at delivery
- Emergency obstetric care
- Timely and effective referral system
- Availability of safe abortion services.

- There are three types of delays that can affect a woman’s chance of surviving an obstetric emergency:
  1. delay in problem recognition and decision making;
  2. delay in reaching a health facility; and
  3. most importantly a delay in receiving care at health care facility.

- Emergency obstetric care is often discussed in terms of basic and comprehensive care that is provided to a woman with obstetric complications.

- There are challenges in addressing EmOC in low-resource settings like lack of standard guidelines in training doctors and their supervision, shortage of continuous supply of drugs and repair of equipment’s in time, infection preventive practices are poor and most skilled obstetricians prefer to practice in urban settings.

- Quality EmOC poses unusual challenge because EmOC must be available 24 hours. a day and 7 days a week to be maximally effective. This is an emerging concept of rural obstetrician to reduce maternal mortality.

- The Federation of Obstetric and Gynaecological Societies of India (FOGSI) and its academic wing, ICOG have commenced a certification course in EmOC to develop skilled personnel to reduce maternal mortality in rural areas. This is competency based course of 16 weeks in comprehensive EmOC and 3 weeks course in updating knowledge of those doctors working in rural areas with not sufficient skills in EmOC.

- With 700 public sector obstetricians and more than 20,000 public sector nonspecialized medical officers in rural areas, the vision of the project is massive. FOGSI aims to establish high quality training centers in each state of India to train rural non-specialized doctors in comprehensive EmOC.

- Government of India has supported FOGSI/ICOGs efforts of setting up EmOC training centers. This will help in making many first referral centers and district hospitals competent in providing emergency obstetric care. Hopefully, this public-private partnership will help to reduce maternal mortality in India.

BIBLIOGRAPHY

Family Welfare and Contraception
INTRODUCTION

Since antiquity men and women have desired to regulate their fertility. Studies have shown that having a baby is the least frequent motivator for having sex for most people.\(^1\)

The earliest written references of contraception can be traced back to Egyptian medical manuscript *Ebers Papyrus*, Latin works of Dioscorides, Greek writings of Soranus and Arabic works of Al Razi and Avicenna. The various methods of contraception described in these ancient scriptures ranged from unscientific ineffective methods to reasonable scientific methods. Most of the birth control methods were developed by hit and trial. As dissemination of contraceptive knowledge was considered illegal and punishable in those times it was secretly passed from generation to generation.

A brief overview of the history and development of various contraceptive methods is described below.

NATURAL METHODS OF CONTRACEPTION

These methods have played an important role in family planning since ancient times. Abstinence, withdrawal, safe period method and breastfeeding are some natural methods of contraception.

Abstinence

People in ancient times believed pregnancy to be a magical event and had no idea of a connection between vaginal intercourse and reproduction. However, gradually as this relation was established, abstinence for birth control was promoted. Feminists in America promoted abstinence within marriage in 1870s, which resulted in an epidemic of sexually transmitted diseases (STDs).

Outercourse

Outercourse or alternatives to penile vaginal intercourse like masturbation were condemned by Early Christian Church. During the same time in India, Mallinaga Vatsayayana (400 CE) wrote *Kamasutra*, an Encyclopedia of procreative and nonprocreative sexual practices. It was translated in English by Sir Richard Burton in 1883 and circulated secretly amongst members of British Kamasutra Society. In 1960s this manual was published in US and became the bible of sexual revolution at that time.\(^2\)

Outercourse was revived in America in 1940s and 1950s but lost its popularity in 1960s with the availability of pill. In early 1980s, outercourse regained its popularity with the emergence of AIDS.

Withdrawal

It is one of the oldest methods of birth control. Coitus interruptus is the Latin name for withdrawal. Withdrawal was considered a sin by ancient Jews and Christians. However in 18th and early 19th centuries it was one of the most popular methods of birth control in the world.\(^3\)

The Catholics and Muslims have a religious sanction for coitus interruptus.
Fertility Awareness Based Methods

Avoidance of intercourse in fertile period for contraception has been practiced by the ancient Romans, Greeks, Africans and Hindus. However, the understanding of the fertile period at those times was inaccurate. The ancient Hindus believed that the most fertile period of a woman was just after or during periods. It was in 1929 Knaus from Austria and Ogino from Japan found that ovulation occurs 12–16 days before the next period. In 1960s Australian doctors John and Evelyn Billing came up with Billings’ cervical mucus method for identifying fertile period.\(^3\)

Lactational Amenorrhea Method

Extended breastfeeding has been used by women to space their pregnancies since prehistoric times. However, affluent Western women had higher fertility as they depended on their slaves for breastfeeding. Even today breastfeeding is more prevalent amongst poor rural women compared to urban dwellers. It provides protection to a significant number of fertile women in developing countries.

BARRIER CONTRACEPTIVE METHODS

In earliest times people used various plant and animal products to prevent pregnancy. Some substances used to block the cervix and absorb semen were vegetable seed pods, plugs of grass and crushed roots, sea weed moss, bamboo, empty halves of pomegranates, squeezed halves of lemon, sponge, tissue paper, bee wax, wool, rock salt, etc.\(^4,5\) With the advent of intrauterine devices (IUDs) and oral contraceptive pills (OCPs), barrier contraceptives became less popular. However, in 1980s with the emergence of AIDS they regained their lost popularity.

Condoms

The use of condom during sexual intercourse can be traced back to 12,000–15,000 years to a painting on the wall of a cave in France.\(^6\) Egyptians are considered to be the pioneers in the use of condoms for protection against STDs. The invention of condom is controversial. Several reports suggest that condom was named after Dr Condom who lived during the reign of Charles II in 18th century and recommended it to the King for protection against fathering illegitimate children and STDs.\(^7,8\) Others believe that the word condom was derived in 1717 from the Latin word “Condus” which means a receptacle.

The various milestones in the history of development of condoms are as follows:

- **19th century**: In 1843, Charles Goodyear and Hancock patented the vulcanization of rubber and introduced rubber condoms in 1870.\(^8,9\)
- **20th century**:
  - Earliest teat ended condoms were manufactured in 1901 by the trade name of “Dreadnought”.
  - Latex condoms were manufactured in 1930s.
  - Lubricated condoms were made available in 1960s. Silicon was used to produce semi-dry lubricated condoms.
  - In 1994, female condom became freely available in US.
- **21st century**: Female condom became available in India in 2007.

Japan leads the world in usage of condom followed by Scandinavian countries. Major condom producing countries are Japan, Great Britain, US, India, West Germany, Hungary, Korea and Thailand.

INTRAUTERINE CONTRACEPTIVE DEVICES

The discovery of modern IUD can be traced back to the Arabs who inserted pessaries into uteri of their camels to protect them against pregnancy during long journeys through the desert. The various milestones in the development of IUDs are as follows:

- **9th century**: A Persian physician recommended insertion of a paper wound tightly as a probe tied with a string and smeared with ginger water into cervix for contraception.
- **11th century**: Islamic scientist Avicenna used intrauterine pessaries for contraception in women.
- **19th century**: Stem pessaries with small caps which extended into uterus and blocked the cervix were used. They were made of wood, glass, silver, gold and ivory.
- **20th century**:
  - Dr Carl Hollweg of Germany in 1902, introduced wish bone shaped pessaries. They were associated with severe pelvic infection.
  - In 1909, Richard Richter from Germany introduced a ring shaped IUD of silkworm gut.
  - In 1926, German physician Dr Ernst Grafenberg introduced the first widely used ring shaped IUD of silkworm gut and silver wire.\(^10\) This IUD was without a tail.
  - In 1934, T Ota of Japan introduced a ring shaped device with a small disc in the center attached to the ring by three spokes made of gold or gold plated silver.\(^11\)
  - In 1936, Grafenberg and Ota rings were abandoned due to high risk of pelvic infection reported by European doctors.
  - In 1959, Oppenheimer of Israel and Isihama of Japan made the Ota and Grafenberg rings of plastic.
  - In 1962, Lazav Margulies and Jack Lippe from New York introduced IUDs made up of polyethylene, a biologically inert material.\(^12\) These devices were known...
as Marguiles coil and Lippes loop. Lippe also added barium sulfate to make it radiopaque and attached fixed nylon threads to it. These were followed by the introduction of several inert IUDs like Birnberg bow, soft coil, double coil, steel rings, etc.
- In 1967, Lernes and Davis designed the Dalkon Shield which became popular in US, but was later withdrawn due to severe infection and deaths associated with it.
- In 1969, Jaime Zipper and Howard Tatum developed medicated devices.
- Early 1970s saw the marketing and wide acceptance of first generation of medicated IUDs all over the world.
- In 1974, Multiload Cu 250 and hormone releasing IUD Progestasert was marketed. Progestasert was later replaced by a longer lasting LNG 20. It was popular in US and France.
- In 1979–1982 2nd generation Copper releasing IUDs with improved life span and effectiveness were introduced. They had silver core copper wires or sleeves.

Intrauterine devices are widely used all over the world. Almost one-third of users are from China alone. In developed countries, IUDs are most widely used in Europe. They are not very popular in US, Canada, Australia, New Zealand and Japan. Inert IUDs are still used in China, Indonesia, Pakistan and Turkey.

**HORMONAL CONTRACEPTIVES**

Women all over the world used herbs for preventing pregnancies. Over the years researchers have discovered a scientific basis of these herbs in preventing pregnancy. Pomegranate was one of the first oral contraceptives widely used by Greek women. Women in tropical India and Sri Lanka ate papaya to prevent pregnancy which was later found to contain an enzyme Papain which interacted with progesterone to prevent pregnancy. Generations of Mexican women ate wild yam to prevent pregnancy and later Russell Marker extracted progestin from this wild yam.

**Oral Contraceptive Pills**

Milestones in the development of OCPs are listed below:
- **20th century:**
  - In 1940s and 1950s Margaret Sanger followed the research on oral contraceptives by scientists Gregory Pincus and Min Chueh Chang.
  - The first successful clinical trials of the hormonal pill were conducted by Dr John Rock, eminent catholic gynecologist in 1956.
  - In 1960, FDA approved a combined OCP Enovid
  - From 1965–1975, studies established a relationship between OCPs and certain major complications like thromboembolic events, death, etc.
- Low dose pills with a reduced dose of estrogen and 2nd generation progestin were introduced in 1970s. These pills were safer.
- Noncontraceptive benefits of OCPs like prevention of ovarian cysts, ovarian and endometrial carcinoma, dysmenorrhea, etc. were highlighted in the period 1975–1985.
- Multiphasic pills with further reduction in dose of hormones per cycle and side effects were introduced in 1980s.
- Low dose pills with 3rd generation progestin and a further reduction in side effects were introduced in 1990s. Mini pills were also introduced during this period.
- **21st century:** Newer pills with decreased side effects and better efficacy, like drospirenone, seasonale, seasonique, etc. were introduced.

**Depot Medroxyprogesterone Acetate**

Soon after the pill was approved by FDA, an effort to develop a method to avoid daily intake of pill was made. The milestones in the development of injectable contraceptive—depot medroxyprogesterone acetate (DMPA) are described as below.
- **20th century:**
  - DMPA was submitted for the Food and Drug Administration (FDA) approval in 1967, which was delayed due to increased risk of breast and endometrial cancer documented in dogs and monkeys respectively with DMPA.
  - In 1971, DMPA was used all over the world except USA.
  - In 1988, FDA advisory committee discontinued the studies on dogs after realizing that dogs were pre-disposed to breast cancer.
  - WHO concluded that DMPA does not cause any additional risk of breast or endometrial cancer to women in 1991.

**Norplant**

The initial research on hormonal implants was successfully carried out in animals in 1950s followed by clinical trials on human beings in 1980s.
- **20th century:**
  - Norplant was approved by WHO in 1984.
  - In 1990, FDA approved Norplant.
  - By 1995, a large number of suits were filed against the manufacturer by users claiming that they were not apprised of the side effects. FDA reanalyzed the product and declared it safe and effective. Norplant II was introduced.
EMERGENCY CONTRACEPTION

The concept of emergency contraception is very old. As described in literature women used methods like wiping out the vagina of semen, sneezing and blowing nose several times, jumping backwards several times, forcefully contracting the vaginal muscles. Vaginal douching with chemicals like alum, plant products disinfectants, etc. was another ineffective but popular method used.

Another method of emergency contraception used was to induce menstruation by various herbs. The earliest reference to such herbs dates back to Hippocrates from Athens (460–377 BC). However, some of these herbs are still used worldwide.

The important milestones in the development of safe and effective emergency contraception are described as below:
- **20th century:**
  - In early 1970s, Dr Albert Yuzpe from Canada prescribed birth control pills for emergency contraception. FDA approved first emergency contraceptive pill product in 1998.
  - FDA approved the first progestin only emergency contraceptive pill in 1999.

MALE AND FEMALE STERILIZATION

Tubectomy

Although tubectomy is one of the most popular methods of contraception, it was the last to be accepted socially.

The various milestones in the history of development of tubectomy are described below:
- **17th century:** First tubal ligation was performed in US in 1880.
- **20th century:**
  - Up to 1930s female sterilization was used only for therapeutic indications.
  - From 1950–1960s female sterilization started gaining ground for fertility regulation.
  - Doctors observed the rule of 120 as a prerequisite for carrying out female sterilization till as late as 1960s. According to this rule a women could undergo sterilization only if her age multiplied by the number of her children equaled 120. That is for following a two child norm; the women had to be 60 years old to be eligible to undergo sterilization.
  - In early 1970s laparoscopic sterilization was introduced.
  - First mini laparotomy was performed in Bangkok in 1974.
  - In 1970s and 1980s tubal ligation as a contraceptive method started growing consequent to the scare about the side effects of oral pills and IUDs.
  - In 1990s tubal sterilization became the most popular method of contraception.

Vasectomy

The history of development of vasectomy as a contraceptive method has an association with force and coercion. Earliest references to male sterilization implied removal of testicles and sometimes penis as well. These castrated men guarded the women of royal families. Currently it is the major family planning method in the developed countries like USA, New Zealand, Australia and Canada. Milestones in development of vasectomy are as follows:
- **19th century:** First vasectomy was performed in UK for relieving a patient of swollen prostate in 1894.
- **20th century:**
  - From 1916–1940 Eugen Steinach, a Viennese Surgeon, began performing mass vasectomies with the aim to prevent aging.
  - In 1950s vasectomy was mainly performed to prevent men from performing sex crimes and transmit genetic diseases; however, vasectomy for birth control gradually became acceptable.
  - This movement gained momentum in 1960s and 1970s.
  - No scalpel vasectomy was introduced in China by Dr Li Shuangliang in 1974 and became popular all over the world since 1986.

History of development of contraception unfolds amazing facts about the knowledge of human beings of various methods of fertility regulation since antiquity and their changing attitude towards the same. The knowledge and understanding of the past events can shed light on modern-day issues regarding the same.

REFERENCES

INTRODUCTION

Fertility control is playing a pivotal role in reproductive health care of women. A successful fertility control program will enable us to face the future with an estimated 8–10 billion world population. Proper fertility control will also reduce maternal mortality rate by 25%.

At 00:00 hours of 1st March 2001, population of India stood at 1,027,015,247 comprising 531,277,078 males and 495,738,169 females. India added about 181 million persons between 1991 and 2001 thus outbeating Brazil also which is the most populated country in the world. Population density of India in 2011 was 382 persons/km².

July 2007 statistics showed total population of India as 1,129,866,154 there by adding 1 million and 30 lakhs. Of these, infants and 0–14 years old were 171,356,024 and 15–64 years old were 346,034,565. This indicates that there is long way to go before which we can achieve population stabilization.

Global trends in women’s health are that it is a state of physical and mental health and social well-being. For the first time in 1996 at the International Conference on Population and Development held in Cairo, Egypt, the consensus of gender equality and women empowerment were recognized as reproductive rights.

Women spend 30 reproductive years with 1 or 2 children and have to lead a sexually active role.

There are various Family Welfare Programs which provide a method by which couple can prevent childbirth.

Natural methods of contraception are those which do not use any appliance or medicine. Some of the methods are in vogue from prehistoric times. It is statistically proved that many couple practice natural methods of contraception worldwide.

The reason for greater compliance is that they do not need any medical appliance or medicine, involve no cost, can be practiced most secretly and without any religious bar.

With the increasing prevalence of sexually transmitted diseases (STDs) the role of natural and more so barrier methods has become important.

Various methods of contraception can be classified as:

• Natural methods
  - Natural family planning (NFP) methods
    - *Fertility awareness-based method (FAB):* This form of contraception includes all family planning methods that attempt to identify fertile time each cycle and then modify sexual behavior. When FAB methods involve sexual abstinence during the fertile time, this technique is called *natural family planning* whereas when these methods involve occasionally using a barrier method during the fertile time, the method is called *fertility awareness-combined methods—FACM.*

Because the ovum is probably susceptible to successful fertilization for only 12–24 hours after ovulation, periodic abstinence has intuitive appeal as a means of birth control. Pregnancy rates, however, with various methods of periodic abstinence have been estimated from 5 to 40 per 100 woman years. In other words, the unwanted pregnancy rate during the first year of use is approximately 20%.

• Lactation amenorrhea method (LAM)
• Withdrawal method
• Barrier methods of contraception.
Natural Methods of Family Planning: Barrier Contraception

NATURAL FAMILY PLANNING METHODS

Previously they were referred to as “safe period” and “rhythm period” based on periodic abstinence. In 1982, WHO advocated them to be referred to as “natural family planning methods”.

Natural family planning methods refer to methods of planning and preventing pregnancy by observing the naturally occurring symptoms and signs of the fertile and infertile phases of menstrual cycle.

Natural family planning has been in practice for ages. Of course the concept of correct ovulation time was not known.

In 1929, “Knaus” of Austria and Ogino of Japan found that ovulation occurs mostly between 12 days and 16 days. NFP methods are based on the premise that coitus should be avoided during this fertile period, timed correctly. Fertile phase is detected by:

- Rhythm method
- Basal body temperature (BBT) method
- Cervical mucus changes
- Symptothermal method correlates cervical mucus changes in BBT and intercourse in a chart form.
- Ultrasound follicular study detects ovulation time and is fool proof and convenient.

The Two-day Method

The two-day method has been developed by the Institute of Reproductive Health of Georgetown recently. It is a newly developed type of FAB method where women can determine whether they are fertile on any given day based on the presence or absence of cervical secretions. Cervical secretions are the key to women’s fertility without which sperms have difficulty traveling to the egg.

The two-day method is appropriate for women with cycles of any length, regardless of regularity, and suits couples who can avoid sex for about 10-15 days per cycle.

To use this method, a woman asks herself two questions each day:
1. Did I notice cervical secretions today?
2. Did I notice cervical secretions yesterday?

If she noticed secretions of any type either that day or yesterday, she should consider herself fertile and avoid unprotected sex. If she did not notice cervical secretions for two days consecutively, she would be unlikely to get pregnant from sex taking place that day. This is a simpler way of identifying the fertile days to either the Billing’ ovulation method or symptothermal method, which also involves observations of cervical secretions. Failure rate from correct use is 4% in 1 year and 14% from typical use.

After initial counseling, most participants (over 96%) are able to detect the presence or absence of cervical secretions. However, although simple this two-day method needs wider trial.

The Persona

Natural family planning enters the age of technology. Persona is basically a microcomputer attached to a microlaboratory. It is based on measurement of levels of luteinizing hormone and estrone-3 glucuronide (E3G) in early morning urine. Women can get an idea of ovulation time by dipping the test stick in her urine. It is widely used in UK and European countries.

With perfect use the failure rates are 6 per 100 woman years. It has to be perfectly programmed and is suited for couple who would follow NFP.

Natural Family Planning methods are applicable without any financial commitment and do not disturb the menstrual cycle. Recent studies in 1993 by WHO ruled out any chromosome or congenital anomalies as a consequence.

New technologies of ovulation prediction involve digital and electronic thermometers and most prefer the follicular study for pin pointing ovulation.

Lactational Amenorrhea Method

This could be effective traditional and popular concept when lactation is the only method of nutrition to the baby. The additional benefits are the antibodies in colostrum which are beneficial to baby. The raised level of prolactin inhibits LH but has no effect on FSH. The antifertility effect of prolactin during nursing may be due to erratic ovulatory cycle. The failure rate is unpredictable and is effective for 6 months only.

Additional benefit is it helps develop bonding between mother and child. Also, it helps in preventing development of breast cancer in later years.

Lactational amenorrhea method has got a very good place as a method of contraception in developing countries.

Counseling

All mothers following LAM should be encouraged to breastfeed fully. They should be informed that:

- Sexual intercourse during lactation is not harmful
- Breastfeeding should not be discontinued to start the use of contraception
- While breastfeeding gives protection against pregnancy, it is difficult to predict precisely the duration of lactational infertility of each woman
- Amenorrhea gives high degree of protection against pregnancy in fully nursing women during the first 6 postpartum months
- Breastfeeding on demand in the day and night can defer the onset of menses and fertility
- The risk of pregnancy increases with the first postpartum menses, the introduction of supplementary milk or food to the infant and after about 6 months of delivery
- Supplementary feeding is not recommended in the first 6 months unless there is affection of infant growth.
• Other contraceptive measures should be used as soon as any of the risks mentioned comes to be present or earlier if a woman wants better protection against pregnancy. The above points of counseling are based on the statement of the IPPF International Medical Advisory Panel issued in November 1989.

**Use Effectiveness**

Failure rate of LAM (for 6 months only) is less than 2% when correctly and consistently used but it is more otherwise. Many authorities believe nowadays that use effectiveness of lactational amenorrhea in fully breastfeeding mothers is as good as that of oral pills and barrier contraceptives, particularly in the first 6 months.

**Advantages**

• Lactational amenorrhea method effectively controls pregnancy for at least 6 months and perhaps longer if a woman keeps breastfeeding often, day and night.
• It can be used immediately after delivery.
• There is no interference at the time of sexual intercourse.
• No extra cost is needed for family planning or feeding the baby.
• No supplies or procedures are needed to prevent pregnancy.
• There are no hormonal side effects.
• The breastfeeding practices required by LAM have other health benefits for mother and baby:
  – It provides the healthiest food for the baby
  – It protects the baby from life-threatening diarrhea
  – It protects the baby from diseases like measles and pneumonia by passing on the mother’s immunities to the baby
  – It helps to develop a close relationship between mother and baby
  – It protects the mother from diseases like subinvolution of the uterus, fibroadenosis and fibroadenoma of the uterus. Breastfeeding reduces risks of breast cancer and epithelial ovarian cancer.
• The risk of breast cancer is reduced by 4% for each year of lactation, according to an analysis of 47 epidemiologic studies in 30 countries. This reduction is essentially the same in developing and developed countries. In addition, the risk of breast cancer is reduced by 7% for every birth a woman has. The incidence of breast cancer is much lower in developing than in developed countries, the study suggests that the larger families and patterns of prolonged breast feeding, typical in the developing world, explain much of the difference.

**Disadvantages**

• The effectiveness of LAM is not certain, and it is less acceptable.
• Frequent breastfeeding may be inconvenient or difficult for some women especially working mothers.
• It does not provide protection against STDs including HIV/AIDS.
• If the mother has HIV (the virus that causes AIDS), there is some chance that the baby will also be infected. Even so, in most parts of the world, particularly developing countries, babies are more likely to die from infectious diseases than from HIV in breast milk. Therefore, WHO recommends that a woman with HIV should breastfeed, but where the risk of infectious disease to the baby is slight and otherwise safe, affordable food is available, infected mothers should adopt a safe alternative method of contraception.

**Eligibility Criteria for Lactational Amenorrhea Method**

**Indications**

In general, most women can use LAM safely and effectively if they:
• Smoke cigarettes
• Are young or old
• Are fat or thin.

**Relative Contraindications**

Women with the following conditions can also use LAM:
• Benign breast disease
• Headaches
• High blood pressure
• Varicose veins
• Valvular heart disease
• Diabetes
• Iron deficiency anemia
• Gallbladder disease
• Malaria
• Sickle cell disease
• Thyroid disease
• Uterine fibroids.

**Absolute Contraindications**

Lactational amenorrhea method cannot be used under the following conditions:
• Baby 6 months or more old
• Mother cannot fully or near fully breastfeed day and night
• Menstruation starts (bleeding for at least 2 days after 8 weeks of childbirth)
• Mother being treated with mood-altering drugs, reserpine, antimetabolites, cortisone, radioactive drugs, cyclosporine and anticoagulants
• Viral hepatitis of mother
• Mother has HIV/AIDS (unless babies cannot be artificially fed properly).
Withdrawal Method

Coitus interruptus implies discharge of semen outside the female genitalia at intercourse. It is one of the oldest methods, practiced by primitive tribes also. There is no religious taboo. Combined with barrier method, NFP is the most effective for family planning. Motivation and proper technique by counseling go a long way for family welfare measures. As even one drop of semen can deliver many spermatozoa, it is not a fool proof method.

BARRIER METHODS

Barrier contraception was the main method of birth control in 1950s. With the introduction of pills and intrauterine devices their use declined. Lately with the fear of STD which are on the rise, the barrier contraceptives are becoming more and more popular.

The male condom is the most widely used and most popular method of contraception in the world.

It is highly acceptable in the developing countries including remote villages as there is no role of technical personnel.

The condom is the most effective method of contraception with failure rate being 2–3% per 100 women years. Addition of spermicides adds to the efficacy.

Condom is the oldest and most widely used birth control device in the world supposedly invented by Dr Condom for King Charles II and scientifically recommended by Italian physician Dr Fallopio in 1564. Later it evolved to the present form, with invention of latex in 1930s which revolutionized the concept.

The arrival of polyurethane condom is welcomed, due to added advantages over latex condoms. It is thin, odor free and with nonallergic effect. It is not corroded by oil-based lubricants.

The non-oxynol-9, a spermicide used as coating is being discontinued due to irritable reaction.

Condom use increased remarkably throughout the world as prevention measures against STDs and AIDS.

The contraception by vaginal sponge has been withdrawn due to the high incidence of anaerobic infection and spermicidal gel not based on non-oxynol-9.

A number of over the counter diaphragm/cervical cap devices (for example, Lea’s shield, Fem gel) may be marked shortly.

Barrier contraception is the main method of birth control and is being used more and more for the fear of STDs and AIDS.

Research should be continued to improve the quality and the type of barrier contraception.

The added advantages are availability without prescription and for elderly couples and adolescents with infrequent coitus.

Condom use provides protection from amniotic infections during pregnancy. It may reduce the chance of developing cervical dysplasia and cancer cervix at a later stage; as one of the theory is that smegma may be the cause of carcinoma cervix.

Female condoms are now available and usage can be propagated. Some of them are hormone impregnated and have dual advantage.

Proper counseling of the usage may further reduce the failure rate.

Counseling: Its role is crucial in any method of family planning. Enough time has to be spent and counseling to be done to the point, leaving the option of the method to the client.

CONCLUSION

Natural contraception has great potentiality for the control of population in India; mainly because they can be practiced without any special training and medical personnel. Motivation and propaganda are the need of the hour. Frequent and prolonged feeding without supplementary feeds to the baby with mid cycle abstinence is recommended. Barrier contraception and more so condom usage are helpful for their role in preventing STDs and AIDS.

Continued research to improve the quality of condoms should be undertaken.

BIBLIOGRAPHY

9. The essentials of contraceptive technology. 11-1-11-18, 5-12-11-11-18.
INTRODUCTION

The control of a woman’s procreative potential has advanced considerably over the past four decades. The introduction of newer, cheaper, safer and highly effective contraceptive agents following extensive research has not only led to increased awareness but a much higher acceptability amongst our population for the practice of fertility control.

As societies become more affluent, fertility decreases. This decrease is in response to the use of need-based contraception. Contraception is not new, but its widespread development and application are new.

An often asked question is “Why do we need contraception?” The answer is rather simple and short, “To avoid unwanted pregnancies!!” In addition, the regular practice of contraception, helps a couple to space their children and also allows a much needed rest to the “new” mother.

This chapter will briefly touch upon the various steroidal and nonsteroidal contraceptive methods presently available.

Steroidal Contraception

- Oral contraceptive pill (OCP):
  - Female
  - Male
- Injectable contraception
- Hormone-releasing intrauterine contraceptive device (IUCD)
- Others: Emergency contraception (EC)

Nonsteroidal Contraception

Temporary

- Natural methods of contraception
- Barrier contraception
- Oral contraceptive pill:
  - Female
  - Male
- Intrauterine contraceptive device
- Implants
- Vaginal rings

Permanent

- Female sterilization
- Male sterilization

Future Contraceptives

Within 2020 AD

- Gonadotropin releasing hormone (GnRH) analogs
- Antigestogens
- Patches
- Vaccines
- Male fertility regulation

Beyond 2020 AD

- Regulatory peptides
- Gene therapy
STEROIDAL CONTRACEPTION

Female Oral Contraceptive Pill

The OCP is a widely accepted and most effective method of fertility control, with over 100 million women using OCs all over the world. With the availability of newer progestogens like desogestrel and gestodene, coupled with lowered doses of estrogen (20 mg), the combined OC (COC) pill has made inroads in our country as well.

Oral contraceptive pills are broadly divided into two groups:
1. Combined OC pill
2. Progesterone-only pill (POP).

Combined Oral Contraceptive Pill

These are of two types:
1. Monophasic pill
2. Multiphasic pill.

Monophasic Pill

These pills contain an estrogen and a progestogen in the same amount in each pill. The most commonly used estrogen in the OCP is ethinyl estradiol (EE). The only other estrogen, which was tried with limited success in the earlier OCP was mestranol (3-methyl ester of EE), later discarded due to its higher risk of thromboembolism, and weak action as a result of its prior metabolism to EE in the body before eliciting its pharmacological action of inhibition of ovulation. The progestogens that are commonly used in OCs are norgestrel, levonorgestrel, desogestrel, gestodene or norgestimate. OCs can be broadly classified as low-dose or high-dose pills depending upon the EE content in each pill:
- Low-dose pill: EE content less than 0.05 mg (50 µg)
- High-dose pill: EE content of 0.05 mg (50 µg) or more.

High dose OCs have now been almost completely replaced for regular use, due to their greater side effects and major complications. However, they are still being used in the developing countries for 1–3 cycles, despite warnings of cardiovascular and other hazards.

In addition, a recent classification of COC pills based on epidemiologic studies have been proposed:
- First generation (high-dose) OCs: Products containing 50 mg or more of EE.
- Second generation OCs: Products containing levonorgestrel, norgestimate, and other members of the norethindrone (NET) group (norethindrone acetate, norethynodrel, ethynodiol diacetate, lynestrenol, norgestrel) and 30 or 35 µg EE.
- Third generation OCs: Products containing desogestrel or gestodene with 20 or 30 µg EE.

Although every attempt is being made to bring down the dose of EE to 15 µg, and even to 10 µg in the COC pills to minimize the side effects of estrogen, the only problem anticipated is whether such measures will provide acceptable cycle control, in addition to contraception. Extensive research is underway in this area at present.

- Spironolactone analog: A new progestin called drospirenone (DRSP) is derived from 17-α spironolactone, an analog of spironolactone. It has antiandrogenic and antimineralocorticoid activities. OCs containing DRSP and EE have been found to be highly effective and provide a safety level equivalent to that of other OCs. They also lessen acne, seborrhea and premenstrual syndrome. It is also being marketed as “Yasmin”.

Multiphasic Pills

These phasic formulations employ low doses and variable amounts of estrogen and progestogens in two (biphasic) or three (triphasic) periods of the menstrual cycle. The dose of the progestogens is low in the beginning and higher at the end, while the estrogen remains either constant or rises slightly in midcycle. The total dose of both steroids in a whole cycle is less in these pills.

Sequential pills, which contained only estrogen in the first 14 tablets and combined estrogen and progestogens in the next 7 tablets, have been withdrawn from the market because of high actual or probable incidents of endometrial carcinoma.

Choice of Estrogen and Progestogens in COC Pills

The universally accepted choice of estrogen in the COC pill is EE, as it provides consistent inhibition of ovulation and good cycle control in doses of 20–30 µg. The choice of progestogens in the present era depends upon not only in providing effective contraception but also in the lipid-friendly profile and positive health benefits (decreased androgenicity) of these molecules. The preferred progestogens are desogestrel and gestodene, although a large chunk of the COC pills prescribed contain levonorgestrel. The hazards attributed to the usage of the older progestogens having higher androgenicity are acne, oily skin, mild to moderate psychosexual disorders (depression, lassitude, decreased libido), negative effects on coagulation and lipid profile.

Mechanism of Action of COC Pills

- Inhibition of ovulation: This mechanism works by suppressing hypothalamic releasing factors leading to inappropriate secretion of follicle stimulating hormone (FSH) and luteinizing hormone (LH); estrogen preferentially inhibits FSH and is dose dependent while
Changes in the endometrium:

- This mechanism leads to alteration in the maturation of the endometrium rendering it unsuitable for the implantation of the fertilized ovum. The endometrial stroma becomes edematous and decidualized, while the glands become atrophic with less secretory activity.

- Changes in the cervical mucus: The cervical mucus becomes scanty, viscous and cellular with low spinbarkeit and no ferning. These changes impair sperm transport and penetration.

Effectiveness

Combined OCPs are very effective. The failure rate when correctly and consistently used is only 0.1% or 1 per 1,000 in the first year of use. The typical failure rate, as is commonly used, is 1.8%, which may increase to 8% or even more. Multicentric studies conducted by the World Health Organization (WHO) have found low-dose pills to be as effective as high-dose ones.

Drug failure: Failure of contraception due to the physico-chemical properties of the drug itself (ingredients, inappropriate or reduced dosage, formulation, etc.)

Method failure: Failure of contraception due to the method of administration of the drug (noncompliance of the patient: irregular pill taking, vomiting/gastroenteritis, nonadherence to pill-free days, etc.).

Pill Taking

Once a decision is taken with regard to the type of COC pill that the concerned woman will take, a decision is taken whether she would like to be a day 1 starter from the first cycle, or a day 5 starter. Starting OCPs from the first day of menses ensures immediate protection. In this regimen, the woman takes a pill every day from day 1 for 21 days, following which a gap of seven tablet-free days are observed, during which her menstruation usually starts. A fresh pack of 21 tablets is started thereafter, and continued cyclically. For a day 5 starter, the woman starts the first pill from the fifth day of the menstrual cycle for a period of 21 days, and continues in this cyclical way every month.

A more rational and effective method is to be a “day 3 starter” from the second month onwards (the woman starting her fresh pack of 21 tablets every month on the third day of her menstruation), as follicular recruitment with further growth of these follicles (up to 10 mm or more), subsequent ovulation and occasional pregnancy have been recorded with the commonly practiced seven tablet-free days.

There is no rational for recommending a pill-free interval (PFI) “to rest”. The serious side effects are not eliminated by PFI. This practice all too often results in unwanted pregnancies.

Irregular pill taking is a common occurrence. The commonly encountered situations are:

- If a woman misses one pill: She should take that pill as soon as she remembers (within the first 12 hours), and take the next pill as usual. No backup is needed.
- If a woman misses two pills in the first two weeks: She should take two pills on each of the next two days; it is unlikely that a backup method is needed, but the official consensus is to recommend backup for the next 7 days.
- If a woman misses two pills in the third week, or more than two pills are missed at any time: Another form of contraception should be used as backup immediately and for 7 days; if a Sunday starter (or, if she is more than 12 hours late with one or more pills), keep taking a pill every day until Saturday, and on Sunday start a new pack; if a non-Sunday starter, start a fresh pack the same day.

Even if no pills have been missed, the woman should be instructed to use backup method for at least 7 days after an episode of gastroenteritis.

Benefits and Advantages

- Prevention of pregnancy
- Cycle control
- Noncontraceptive benefits:
  - Cure of menstrual disorders like dysmenorrhea and ovulation pain (Mittelschmerz), some cases of polycystic ovarian disease
  - Protection against ovarian cancer by 40%
  - Protection against endometrial cancer by 50% (prevention of choriocarcinoma indirectly by preventing pregnancy)
  - Protection against benign tumors: Reduction of benign breast diseases like fibrocystic disease and fibroadenoma (25%), functional ovarian cysts (50%), corpus luteum cysts (80%), uterine fibroids (30%)
  - Protection against ectopic pregnancy (50%), pelvic inflammatory disease (50%), anemia (60-80%), endometriosis, acne, hirsutism, rheumatoid arthritis, osteoporosis.

- No affection of future fertility as it is easily reversible; regular ovulation returns within 3 months in 98% of women
- Simple to use, esthetically attractive, does not interfere with the sexual act.

Side Effects

- Minor: Nausea, vomiting, lack of appetite
- Menstrual irregularity: BTB, metrorrhagia, oligomenorrhea, and rarely, amenorrhea
- Breast changes: Edema, heaviness and tenderness
- Headache and migraine
- Chloasma: Hypopigmentation of the face and forehead
• Weight gain
• Others: Leg cramps, dimness of vision, hyperlipidemia.

Drawbacks
• Cost: Relative expensiveness
• Does not prevent sexually transmitted diseases
• Interference with biochemical and biopsy findings
• Myths about OCPs with respect to increased risk of cardiovascular disease and possible carcinogenicity.

Dispelling the Myths
Cardiovascular disease:
• All low-dose oral pills, regardless of the progestogens type, have an increased risk of venous thromboembolism, although the risk is lower than that reported earlier.
• Low-dose OCPs do not increase the risk of myocardial infarction or stroke in healthy, nonsmoking women, regardless of age; almost all myocardial infarctions and strokes occur in users of high-dose pills, or users with cardiovascular risk factors over the age of 35.

Possible Carcinogenicity
Cervix:
• Risk of dysplasia and carcinoma in situ increases with the use of OCPs for more than 1 year; hence, Pap smear surveillance is important, either annually or even 6-monthly for women using OCPs for 5 years or more.

Breast:
• Current and recent use of OCPs may be associated with about a 20% increased risk of early premenopausal breast cancer—this may be due to detection/surveillance bias and accelerated growth of already malignancies
• Previous OC use may be associated with a reduced risk of metastatic breast cancer later in life, and possibly with a reduced risk of postmenopausal breast cancer
• Oral contraceptive use does not further increase the risk of breast cancer in women with a positive family history of breast cancer or in women with proven benign breast disease.

Progestogen-only Pill
Progestogen-only pills or minipills contain small amounts of any one of the commonly used progestogens but no estrogen. These pills are much less used than the COC pills. The most commonly used progestogens are ethynodiol diacetate, NET, levonorgestrel and norgestrel. Recently, etonogestrel (3-keto desogestrel) is gaining wide popularity as an effective and safe POP.

Mechanism of Action
Progestogen-only pills produce their contraceptive effect in three ways:

1. By thickening the cervical mucus plug and making it impermeable to spermatozoa; the effect starts in 2–4 hours and lasts for 20–24 hours.
2. By inhibiting ovulation (60% of cases).
3. By involuting the endometrium making it hostile to implantation.

Indications:
• Lactating women
• Women more than 40 years.

Effectiveness
The average failure rate is 3–10% in the first year of use. When used effectively and consistently in lactating women, the failure rate is only 0.5% in the first year; the failure rates being higher in younger women than their older counterparts.

Administration
Progestogen-only pills should be started 6 weeks after delivery in a fully breastfeeding woman, and no backup contraceptive method (barrier/abstinence) is necessary. In other cases, POPs should be started on the first day of the period and a backup method must be used for seven days, with the POPs taken daily at the same time of the day.

Compositions and Proprietary Names
• Norethindrone: 0.350 mg (Micronor/Noriday)
• Levonorgestrel: 0.075 mg (Neogest)
• Norgestrel: 0.030 mg (Microval/Norgeston)
• Ethynodiol diacetate: 0.500 mg (Femulen)
• Desogestrel: 0.075 mg (Cerazette)

Comments (WHO, 2004) on Use of Progesterone-only Pills
• Pregnancy: No harm to the mother or fetus if POPs are used occasionally
• Adolescents: No definite evidence has been found on the effect of POPs on bone mineral density or bone mass levels.
• Obesity: No decreased effectiveness of depot medroxyprogesterone acetate (DMPA) or Jadella.
• Breastfeeding: There is concern that the neonate may have hormonal effects during the first 6 weeks postpartum. POPs do not affect breastfeeding performance and infant health and growth; nor do they increase depressive symptoms.
• Cervical intraepithelial neoplasia: Among women with human papillomavirus infection, long-term DMPA use (≥ 5 years) may increase the risk of carcinoma in situ and invasive carcinoma.
• Tuberculosis: Rifampicin is likely to decrease POP effectiveness.
Family Welfare and Contraception

- **Fibroids:** POPs do not appear to cause growth of fibroids.
- **Diabetes:** POPs may increase the risk of thrombosis, although less than COCs, in complicated diabetes or cases of more than 20 years duration.
- **Viral hepatitis and cirrhosis:** POPs may affect liver function, although less than COCs.
- **Rifampicin and certain anticonvulsants:** POPs may be less effective in women taking these drugs.
- **Antiretroviral therapy:** POPs may affect ARV therapy in AIDS patients. In these cases, a condom is preferable.

**Continuous Use Oral Contraceptives**

Studies have found that continuous use of monophasic pills reduces the number of times women experience monthly bleeding per year and reduces the number of bleeding days. Continuous use OCs also reduce the side effects including migraines, headaches, premenstrual syndromes, mood changes and heavy or painful menstrual bleeding which women experience while taking COCs for 3 weeks with 1 week off. However, in continuous use OC users incidence of breakthrough bleeding (BTB) or spotting is more which diminish after about 8 or 9 months of use.

One formulation, “seasonale” is packaged specifically for continuous use and is the US Food and Drug Administration (US FDA) approved. It contains 0.15 mg l-levonorgestrel and 0.03 mg EE (same doses as those of low-dose pills). Women take a pill every day for 84 days (12 weeks), and then take hormone-free pill for 7 days. This results in 4 withdrawal bleeds a year rather than 12. Seasonale has become a popular method of contraception in recent years. No extra pathologic change in lipid profile and endometrium has been found so far.

**Male Pill**

Within the next 5 years, a pill designed for male contraception could be available commercially. This is based on systemic administered steroid hormones which act by inhibiting the secretion of LH and FSH, thereby leaving testosterone secretion intact, thus rendering the man infertile but not impotent.

**Injectable Contraception**

Injectable contraceptives contain synthetic hormones that are administered by deep intramuscular injection, and are considered safe, effective and reversible contraception for most women. The injectable contraceptives that are available are:

- **Progesterone-only injectables (long acting):**
  - DMPA as a 1 mL injection containing 150 mg DMPA in an aqueous microcrystalline suspension, given once every 3 months
  - Norethisterone enanthate (NET-EN) as a 1 mL injection containing 200 mg DMFA in an oily preparation, given once every 2 months.

- **Combined injectables (short acting):**
  - Cyclofenyl Cycloprovera contains 25 mg of medroxy-progesterone acetate and 5 mg of estradiol cypionate, administered once a month
  - Mesigyna/Norigynon contains 50 mg of NET-EN and 5 mg of estradiol valerate, administered once a month

**Hormone-releasing Intrauterine Contraceptive Devices**

There are two hormone-releasing IUCDs:

**Progesterone IUCD**

This device called Progestasert is T-shaped, made of ethylene vinyl acetate (EVA) copolymer impregnated with barium sulfate. The vertical shaft is fitted with a capsule containing 38 mg of progesterone dispensed in silicone oil, delivering progesterone to the uterus at the rate of 65 µg per day. The contraceptive efficacy lasts for 1 year, although there is a possibility of increase of ectopic pregnancy. The use of Progestasert also leads to a decrease in menstrual loss.

**Levonorgestrel IUCD**

It is the “Gold Standard” IUCD amongst the hormone-releasing IUCDs, and is known by different names like LNG-20, Levonova and Mirena. It is long acting when compared to Progestasert, with a contraceptive effect lasting for 5 years, the pregnancy rates being very low at 0.1–0.4% per 100 women year in the first year. It is also T-shaped with a capsule on the stem, the core of the capsule containing a mixture of silicone rubber and 40–60 mg of levonorgestrel (LNG), releasing 20 µg of LNG per day. It has a protective effect against ectopic pregnancy, in addition to decreasing menstrual blood loss, sometimes resulting in complete amenorrhea, and is hence being actively promoted as treatment for menorrhagia.

**Emergency Contraception**

Emergency contraception refers to a method of contraception, used as an emergency measure to prevent unwanted pregnancy following unprotected intercourse or expected failure of contraception. EC is also referred to as “postcoital” or “morning-after” contraception, or interception.

Unwanted pregnancy can arise due to many reasons for which a woman may opt for EC. They are:

- Unplanned intercourse
- Forced intercourse
- Rape
- **Condom:** Slipped out/tore during coitus
• **OCPs:** Irregular pill taking/three or more missed pill without using any other form of contraception  
• **DMPA:** More than 2 weeks late for repeat injection  
• **NET-EN:** More than 1 week late for repeat injection

Emergency contraception can be provided by the following ways:
- Hormonal tablets
- Intrauterine contraceptive devices
- Others: Mifepristone (RU-486).

### Hormonal Tablets

Also known as emergency contraceptive pills, these are either COC pills or POP pills.

**Methods:**
- Two conventional COC pills (50 mg EE + 250 mg LNG) within 12 hours (1st dose) of unprotected intercourse, and then repeat the same dose 12 hours later (2nd dose): Yuzpe regimen.
- Four “low-dose” COC pills as 1st dose within 12 hours, 4 more 12 hours later (2nd dose).
- **POP:** 750 mg LNG as 1st dose (within 72 hours of unprotected intercourse) and repeat the same dose 12 hours later (2nd dose).

**Mode of action:**
- Delay or inhibit ovulation
- Alter tubal transport of sperm/egg or zygote (if fertilization has occurred).
- Impair endometrial ripening (makes the endometrium hostile for implantation of the embryo).

**Success rate of EC (when administered correctly):**
- Yuzpe regimen: 97–98%
- POP: 99%
- Cu-IUCD: 99.9%.

**Problems:**
- Nausea, vomiting (2%) with Yuzpe regimen
- Abdominal cramps
- Delayed periods
- Spotting.

**Intrauterine contraceptive devices:** Insertion of a copper (Cu) containing IUCD (Cu-T 200, Multiload Cu-250, Multiload Cu-375, Cu-T 380 series, etc.) within 120 hours (5 days) of unprotected intercourse. This not only provides effective interception (99.9%) but also can be continued as contraception for 3–5 years, depending on the type of IUCD used. It can only be used in parous women.
- **Mifepristone:** Mifepristone (RU-486) is a potent anti-progesterone agent (with five times more affinity for the progesterone receptor than progesterone itself). It has been used extensively and successfully as an intercourse since 1988. The original dosage schedule used was 600 mg as a single dose on day 27 of the menstrual cycle. Nowadays, reduced dosages of 50 mg, and even as low as 10 mg, have found popularity as an effective form of interception. In addition, the 10 mg dose regimen produced half the incidence of delayed periods for more than 7 days when compared to those women who were administered 600 mg (18% vs 38%). Ultralow dose therapy with 5 mg is now under clinical trial.

### NONSTEROIDAL CONTRACEPTION

#### Natural Methods of Contraception

Natural methods of contraception are those, which do not use any appliance of medicine. Some of these methods have been practiced throughout the world from prehistoric times. They are mentioned here only for completion, as their individual failure rates are high (10–35% women years), although when used effective and consistently, the failure rate can be lowered. The natural methods of contraception still practiced are:
- **Natural family planning methods:**
  - Rhythm method/safe period
  - Basal body temperature method
  - Cervical mucus method/ovulation method/Billings method
  - Symptothermal method.
- Lactational amenorrhea method
- Withdrawal method
- Others: Vaginal douching; abstinence

#### Barrier Contraception

Barrier contraceptives are family planning methods which act as barriers and prevent the fertilization of the ovum by the spermatozoa. They are of four types:

1. **Condom:**
   - Male
   - Female.
2. **Occlusive caps:** Vaginal diaphragms, cervical caps, Vault cap, Vimule cap.
3. **Vaginal sponge:** Nonoxynol-9.
4. **Spermicides:** Nonoxynol-9; chemical suppositories; foam tablets; aerosol creams.

#### Male Condom

The male condom is the only known contraceptive proven to prevent sexually transmitted diseases (STDs) and HIV infection which causes AIDS. Various types of latex rubber condoms are available: dry, lubricated, colored, flavored, scented, textured with or without spermicidal incorporation. The condoms are circular cylinders closed at one end with a small teat and open at the other with an integral rim, 15–20 cm in length, 3–3.5 cm in diameter and 0.003–0.007 cm
in thickness. Polyurethane and silicon condoms are now available, although expensive. The typical average failure rate of condom varies from 3% to 12%, but has been reduced to 1%, if a spermicidal product (nonoxynol-9) is used along with the condom. Condoms have a shelf life of 3 years.

**Female Condom (Figs 1A and B)**

The female condom has been a recent development. Various designs have been proposed, including the bikini-condom with its integral latex pouch, and more recently the Janesway panty-condom, with a latex pouch attached to frilly knickers!! The most successful product is Femidom (reality in the USA), first devised in Denmark. It is made of polyurethane and preloaded with an efficient silicone lubricant, 17 cm long, with an open outer end of 70 mm diameter with a ring attached to prevent it advancing beyond the vulva, and a 60 mm diameter inner ring at the inner closed end aiding retention within the vagina (squeezed like a diaphragm for insertion). The whole device thus forms a well-lubricated secondary vagina. Reports about its acceptability are high, although its use effectiveness (95% effective to 1 year of perfect use) is broadly similar to the male condom. The advantages proposed are:

- Over-the-counter method, not requiring fitting by any outsider
- Under the woman’s control
- One universal size
- Women of any age can use it
- Insertable pre intercourse
- Does not require an erect penis at outset
- Male sensations reported to be better than male rubber condom

- Odor free
- Complete barrier against STDs including viruses
- Worth suggesting if local soreness makes sex uncomfortable or during menses or postpartum lochia or during missing pill periods
- Shown to be less likely than the male condom to rupture in use
- Not damaged by any common chemicals.

The problems reported in use are:

- Prominence during foreplay
- The potential for the penis to become wrongly positioned (between the sac and the vaginal wall)
- It is rather noisy in use: Prompting the suggestion to “have the music on”!!

The female condom can be used with both water-based and oil-based lubricants. Male condoms should not be used concurrently because simultaneous use may cause friction that leads to condom slipping, tearing, and displacement. Following use, the female condom outer ring should be twisted to seal the condom so that no semen spills out.

The female condom has an acceptability rate of about 60% for women and 80% for men. However, the pregnancy rate is higher than with the male condom. The female condom has a 0.6% breakage rate. The slippage and displacement rate is about 3% compared with 3–8% for male condoms. In vitro tests have shown the condom to be impermeable to HIV, cytomegalovirus, and hepatitis B virus.

**Cervical Cap**

The Prentif cavity-rim cervical cap was approved for use by the FDA in 1988. The flexible, cup-like device is made of
natural rubber and is fitted around the base of the cervix. It can be self-inserted and allowed to remain in place for up to 48 hours. It should be used with a spermicide applied once at insertion. If properly fitted and used correctly, the cap is comparable in effectiveness to the diaphragm. The cervical cap is relatively costly, and overall, incorrect fitting and/or improper placement make it less effective than the diaphragm plus spermicide.

**Lea’s Shield**

Lea’s Shield (Yama, Inc., Union, NJ) is a reusable, washable barrier made of silicone, which is placed against the cervix (Fig. 2). The device comes in one size, which simplifies the fitting process. It may be inserted any time prior to intercourse and must be left in place for at least 8 hours afterwards. When used with spermicide, and adjusted for age, the reported 6-month life-table pregnancy rate was 5.6 per 100 users.

**Vaginal Sponge**

The most popular vaginal sponge available in the market is Today, a soft disposable foam sponge made of polyurethane, saturated with a powerful spermicide, nonoxynol-9. It is inserted high up in the vagina prior to intercourse, the spermicidal effect lasting for 24 hours (intercourse may be repeated as often as desired during this period). It must be removed and discarded after 8–24 hours but not before 6 hours of the last act of coitus. The failure rate varies between 9 and 27 per 100 women users in the first year. In addition to allergic reactions, vaginal dryness, soreness, the real danger of the sponge is the development of a rare life threatening complication, toxic shock syndrome (TSS). TSS is an extremely serious illness characterized by vomiting, diarrhea, high-grade fever, body rash and ultimately shock, caused by an endotoxin produced by *Staphylococcus aureus*.

**Nonhormonal Oral Contraceptive Pill**

**Female Pill**

The need for a safer alternative to estrogen-progestogen COCs was felt for over three decades. Researchers the world over have been designing and synthesizing nonsteroidal estrogen antagonists that would act by disturbing the delicate balance between estrogen and progesterone at the uterine level without interfering with the synthesis of blood levels. This led to the discovery of Centchroman, which marked a significant breakthrough in the sphere of contraception.

Centchroman is a novel nonsteroidal agent unrelated to any conventionally used contraceptive. Centchroman offers a unique combination of weak estrogenic and potent anti-estrogenic properties. In other words, Centchroman is a selective estrogen receptor modulator (SERM), and mediates its estrogenic effects through its estrogen receptor interaction. Central Drug and Research Institute (CDRI), Lucknow has the unique singular distinction to conceive, research and manufacture this molecule for the first time in the world. Centchroman is truly a “made in India” product.

**Mechanism of action:** Centchroman exerts its contraceptive action by the following ways:

- Acceleration of embryo transport through the fallopian tubes
- Suppression of endometrial proliferation and decidua- lization leading to a dyssynchrony between the embryo and uterine development
- Thickening of the cervical mucus

Centchroman has no effect on the hypothalamo-pituitary-ovarian axis and does not inhibit ovulation.

**Dose and administration:** The accepted regimen is one tablet of 30 mg twice a week for 3 months, followed by one tablet once a week for as long as contraception is desired. The first tablet has to be taken on the first day of the menstrual cycle and more importantly, the tablet should be taken on fixed days and at fixed times. The dosage should be strictly followed irrespective of subsequent menstrual periods.

Centchroman can be safely administered to lactating women after 6 months of delivery as a precautionary measure, although the concentration of the drug is below that of any which can have physiological consequences to the suckling baby.

**Contraindications**

- Polycystic ovarian disease
- Cervical hyperplasia
- Recent history of clinical evidence of jaundice or liver diseases
- Severe allergic states, chronic illness (tuberculosis, renal disease, etc.).
Effectiveness: Pearl index—1.07 (in a phase III study involving 26,899 women months of use).

Male Pill

The male pills, which are in use and under study, are:
- Gossypol
- Triptolide
- Styrene maleic anhydride.

Gossypol, or more commonly referred to as the “Chinese male pill”, has been used in China since 1972. It is a dissequiterpene aldehyde obtained from the seed, stem and roots of the cotton plant, and is now available in a highly purified form. Gossypol produces its effect by inhibiting spermatogenesis, decreasing epididymal sperm motility and affecting the conversion of proacrosin to acrosin. Restoration of fertility on stopping the drug is a problem and is associated with side effects, the most dangerous of which is hypokalemic paralysis seen in 1% of users.

WHO is investigating Triptolide, a compound extracted from the Chinese plant, Tripterygium wilfordii, for its antifertility effect.

Every attempt is being made to find chemical compounds having effects on sperms stored in the epididymis. A phase II clinical trial of a vas deferens injectable male contraceptive has been carried out. 60 mg of an agent containing styrene maleic anhydride (SMA) when administered bilaterally was shown to inactivate spermatozoa all along the length of the vas almost immediately for at least a 12-month-period. The method appears to be safe and yearly injections are required.

RISUG an acronym for “reversible inhibition of sperm under guidance” is a clear polymer gel made of SMA mixed with dimethyl sulfoxide (DMSO). It was developed in the Indian Institute of Technology and the All India Institute of Medical Sciences in India. RISUG is injected into the vas deferens in the testis; it partially blocks the vas, preventing sperms from coming into the ejaculate. It may act in some other way also. Results from Phase I and Phase II clinical trials suggest that use of RISUG is safe and effective as a contraceptive method. Animal studies have shown that sperms reappear when RISUG is flushed out with DMSO or sodium bicarbonate, or noninvasively by massage, vibration and low level electric current. Toxicological studies are being conducted.

Intrauterine Contraceptive Devices

Intrauterine contraceptive devices are an effective, safe and convenient method. They are made of plastic or metal or a combination of both of these materials, meant for insertion into the uterine cavity for contraception.

Indications
- Women who:
  - Want to delay pregnancy for a few years
  - Are breastfeeding
  - Have difficulty using other reversible methods
  - Prefer a method that does not require supervision or action before the act of coitus.

Intrauterine contraceptive devices are typically classified into three categories:
1. Inert IUCDs: Lippes loop, Saf-T coil, Ota ring
2. Copper-releasing IUCDs: Copper-7, Copper-T 200, Copper-T 220C, Multiload Cu-250, Multiload Cu-375, Copper-T 380A, Copper-T 380S.

The Cu-T 380 series is often considered as the “Gold Standard” IUCD amongst the categories mentioned above.

Based on contraceptive efficacy, IUCDs are divided into three groups:
1. Group I: Pregnancy rates greater than 2.0 but not less than 1 per 100 women years (Lippes loop, Copper-7)
2. Group II: Pregnancy rates less than 2.0 but not more than 1 per 100 women years (Multiload Cu-250, Copper-T 220C).
3. Group III: Pregnancy rates less than 1 (mostly less than 0.5) per 100 women-years: Multiload Cu-375, Copper-T 380A, Copper-T 380S, LNG-20.

Mechanism of Action
- Preventing sperms by impeding sperm transport and inhibiting their capacity to fertilize the ova
- Produce an inflammatory or foreign body reaction, which in turn causes cellular and biochemical changes in the endometrium, and in the uterine and tubal fluids.

Advantages
- No systemic undesirable side effects as in OCs
- Reversible: Fertility returns immediately following removal
- One time motivation
- Only one insertion every 3–5 years
- Cost-effective.

Implants

In order to increase contraceptive efficacy without corresponding dose increases, non-oral systems for sustained release of progestogens have been developed. Sustained-release progestogens implants (implantable contraceptives), are a new approach to meeting a worldwide need for more effective and acceptable birth control. This need stems from at least four background problems:
1. Rapid background growth
2. Environmental degradation
3. Persistent poverty
4. Unplanned pregnancy.

The implants which are available at present are non-biodegradable, (polydimethyl siloxane: silastic, EVA) which although are easy to insert, but terribly difficult in comparison to remove. Attempts are now on to discover newer implants, which are biodegradable. The WHO medical eligibility criteria are less restrictive for contraceptive implants than for OCs. In addition, implants are now considered to be probably the most efficacious method of all reversible contraceptives.

The implants currently available are:
- **Norplant**: Six silastic capsules releasing LNG, with a contraceptive efficacy of 5 years.
- **Norplant-2**: Two silastic covered rods releasing LNG, with a contraceptive efficacy of 3 years.
- Implanon consists of EVA rod releasing 3-keto desogestrel (etonogestrel), with a contraceptive efficacy of 3 years.
- Elcometrine Nestorone implant.

**Jadelle or LNG Rod**

This new system of contraceptive implant, the Jadelle or LNG rod, was earlier known as Norplant II. This type of implant as well as Norplant are research products of the Population Council, New York, and are manufactured by Leiras in Finland.

The LNG rod consists of two solid silastic rods, each 44 mm long. A total of 70 mg LNG is dispersed in the matrix of each rod. They are inserted and removed in the same way as the original Norplant, although both insertion and removal are much easier. The daily release of hormone too is almost like that of the original Norplant. The effectiveness and acceptability of the rod is same as that of Norplant capsules.

The failure rate of Jadelle or original Norplant is 0.05% (5 per 1000 women) in the first year of use and the continuation rate at 1 year is 84%.

The main points about the LNG rod are as follows:
- The LNG rod is a new product of its kind.
- It has approved effective life of 5 years rather than 3 years.
- The device is easier to insert and remove than the old Norplant system, as it does not become fragile through prolonged stay in a woman’s arm.

Although the LNG rod has been intensively tested and approved in USA, it is not yet available in the US market at the time of writing although is available through the private sectors in Europe and many developing countries including India.

**Efficacy**
- **Three years cumulative pregnancy rate**: 0%
- **Five years cumulative pregnancy rate**: 1%

**Benefits**
- Effective contraception
- Lower incidence of ectopic pregnancy
- Less lower genital tract infection (vaginitis, cervicitis)
- Less pelvic inflammatory disease.

**Problems**
- **Vaginal spotting/bleeding**: Common within the first year of use.
- **Amenorrhea**: Up to 75% after first year of use (less with LNG).
- **Headache, dizziness, mood changes, acne, weight gain**: 1–10%.

Other nonbiodegradable implants like ST-1345 implant (1 capsule) and Uniplant implant (1 silastic rod with nomegestrol acetate) are still in clinical trials. The main biodegradable implant, a single poly-e-caprolactone capsule with LNG (Capronor) with a contraceptive efficacy for 1 year, is under extensive study and ready for commercial availability. Finally, biodegradable subdermal NET pellets are being used in clinical trials with various ratios of NET to cholesterol (Annuelle: 4 pellets with 90% NET and 10% cholesterol).

**Implants Undergoing Trials and Research**

**ST-1435 single-rod implant or nestorone implant**: The Population Council is now testing a single modified silastic implant using a new progestogen ST-1435 which has contraceptive action and side effects similar to those of LNG. The implant contains ST-1435 crystals encased in a silastic capsule which releases the hormone at the rate of 100 µg/day. Early clinical trials have shown reliable contraceptive effect.

It is designed specifically for lactating women and has completed phase II clinical trial.

**Chinese no. 2 implant**: This system—also called sino-implant—is nearly identical to Jadelle but contains more LNG (150 mg instead of 140 mg).

**Vaginal Rings**

Steroid-containing vaginal rings have been in use intermittently for the last three decades. The vaginal rings available are:
- Levonorgestrel ring
- Progesterone ring
- Etonogestrel (3-keto desogestrel) ring
- ST-1435 ring
- R-2323 ring
- Combined estrogen-progestogen rings:
  - EE and etonogestrel
  - EE and LNG
  - EE and norethisterone acetate.
**Levonorgestrel Ring**

This ring has been tried by WHO since 1980 and are called Varlevo 20 rings or Silastic 382 rings. They are silicone rubber rings with a diameter of 55.6 mm and a cross section of 9.5 mm, and contain 5 mg of LNG with a daily release rate of 329 µg. It acts in three ways:

1. By changing the character of the cervical mucus to make it impermeable to sperms
2. By making the endometrium "out of phase"
3. Inhibiting ovulation (50% of women).

It is left in the vagina for 3 months continuously, after which it is replaced by a new one. The "first pass effect" on the liver is eliminated, lessening some side effects of the OCs. The other advantages are that they are convenient to use and reversible at will. The disadvantages include expulsion during defecation, irregular bleeding or spotting. The failure rate with the device in place is 3.7% women at the end of 1 year. The 1 year discontinuation rate is 50%.

**Hormonal Contraceptive Vaginal Rings**

Vaginal rings are a new method of steroid contraceptives. Some of them have recently been approved by the US FDA, and are on the market in some countries. Combined estrogen and progestogen rings offer good cycle control and deliver hormones more steadily than COCs.

Women can control the use of vaginal rings. A woman inserts the vaginal ring with her fingers in the higher part of vagina. The vaginal ring currently available for contraception is Nuva Ring.

**NuvaRing**

One of the most recently marketed methods is NuvaRing (Organon). It is a soft vaginal ring that release 15 µg EE and 120 µg etonogestrel, the active metabolite of desogestrel, per day as a controlled delivery system. Women keep the Nuva-Ring in the vagina for 3 weeks, and then remove it for 1 week, during which they have withdrawal bleeding. A new vaginal ring is needed for each 4 weeks cycle. If necessary the ring can be removed for intercourse, but it should not be outside the vagina for longer than 3 hours at a time during the scheduled 3 weeks use. When the period of non-use exceeds 3 hours, the manufacturers recommend an additional method of contraception for the next 7 days.

The contraceptive effect of NuvaRing is achieved through inhibition of ovulation. Concomitant use of vaginal antimycotics, spermicides or tampons does not appear to affect efficacy. The metabolic effects of NuvaRing are similar to those of low-dose COCs. The efficacy rate of NuvaRing is like that of COCs—the failure rate after perfect use is 0.3% within the first year of use and 8% after typical use.

One of the disadvantages is ring expulsion without the knowledge of the woman—sometimes resulting in pregnancy. Factors associated with expulsion are prolapse of the uterus cystocele, rectocele and severe or chronic constipation. The side effects include headaches, leukorrhea, vaginitis, nausea and breast tenderness. The high cost of NuvaRing is another disadvantage.

The advantages of NuvaRing include the low doses of hormones, avoidance of gastrointestinal disturbances and a rapid return to ovulation after discontinuation. Moreover, the ring is easy to insert and remove from the vagina; it is generally not felt by the partner during intercourse; it gives the women control without help from medical persons and is well tolerated.

However, NuvaRing is a new contraceptive method and further studies are needed to ascertain the long-term effects.

**Promising Trials and Development**

**Combined estrogen and progestogen vaginal ring**: It is a ring still at the stage of clinical trials and releases a combination of 150 µg of different progestogens, nestorone (ST-1435) and 15 µg of EE per day. The Population Council, with the help of US AID, is developing this ring specifically for use in developing countries. It will be effective for over 12 months. Women would keep the ring in the vagina for 3 weeks, then remove it for withdrawal bleeding and then reinsert the same ring for another 3 weeks. The early clinical trials are promising, and phase III trials are planned in 2005. There were 1.2 pregnancies per 100 women in the first year of use. The side effects were like those of COCs.

**Progestogen vaginal ring**: A vaginal progesterone-only ring called “Progering” has been developed and has been undergoing clinical trials since late 1990s. It contains natural hormone progesterone. These rings are slightly less effective than combined vaginal rings; however, they are very effective in lactating women because breastfeeding itself provides some protection against pregnancy. They do not contain estrogen which can reduce milk production. Each ring releases 10 mg of progesterone daily and lasts for 3 months. Women use these rings continuously for up to 1 year. Bleeding disturbances are common; other effects are almost the same as those of combined vaginal rings.

**Nestorone vaginal rings**: The Population Council is developing another progestogen-only ring containing nestorone (ST-1435), a more potent synthetic progestogen. These rings are particularly suitable for lactating women and provide effective contraception for up to 1 year like progering. However, clinical trials on these rings have lately been suspended.

**Permanent Methods**

- Female sterilization
- Male sterilization
Although a detailed discussion on the permanent methods of contraception is far beyond the scope of this chapter, a brief mention of the common methods in use are given below:

### Female Sterilization
- Minilaparotomy
  - Pomeroy’s technique and its modifications
  - Irving’s technique
  - Uchida’s technique
  - Kroener’s technique
  - Madlener’s technique
  - Parkland’s technique
- Vaginal tubectomy
- Laparoscopic sterilization
  - Falope/Yoon ring application
  - Hulka-Clemens/Fische clip application
  - Bipolar electrocoagulation method

The 10-year cumulative failure rates of female tubal sterilization methods are:
- Unipolar coagulation: 0.75%
- Postpartum tubal ligation: 0.75%
- Silastic (Falope/Yoon) ring: 1.77%
- Interval tubal ligation: 2.01%
- Bipolar coagulation: 2.48%
- Hulka-Clemens clip: 3.65%

### Male Sterilization
- Conventional vasectomy
- “No-scalpel” vasectomy

**No-scalpel vasectomy versus conventional vasectomy**: No-scalpel vasectomy, developed by Dr Li Shungiang of the Sichuan Province in China, is as effective as the conventional approach. Since 1986, this new technique has become more and more popular in many countries in the world. In China, more than 10 million men have undergone no-scalpel vasectomy. The new technique has some definite advantages over the conventional technique:
- The procedure takes less time, about 10 minutes
- Faster recovery
- Improved method of local anesthesia (vas block)—less painful
- Less tissue injury; less bleeding; decreased incidence of hematoma formation; less infection; less postoperative discomfort
- Psychologically a more acceptable procedure as there are no scalpels and stitches involved.

This technique, however, requires good practical training. On the whole, conventional or by the no-scalpel technique, vasectomy is safer, easier to perform, less expensive and has a lower failure rate than female sterilization. In addition, vasectomy reversal is associated with pregnancy rates as high as 70-80%, the best results achieved when the reversal is performed within 3 years of the vasectomy.

### FUTURE CONTRACEPTIVES

**Within 2020**

**Patches**
A new contraceptive method, “EVRA” patch containing EE and norgestimate is under advanced human trials. The patch is applied every week on a woman’s arm, upper chest, abdomen and buttocks, the drugs being released throughout the week. The patch has been found to be very effective, popular with fewer side effects, and expected to be available soon.

**Transdermal contraceptive patch**: A new contraceptive method, the patch, works transdermally by slowly releasing a combination of progestogen and estrogen through the skin. The only contraceptive patch available in the market now is “Ortho-Evra” (also called “Evra” outside USA, developed by Ortho-McNeil Pharmaceutical). It was approved by the US FDA in 1992 and is available in developed countries including USA. This combined patch delivers 150 µg of the progestogen norelgestromin and 20 µg of EE per day. A women wears a patch for 1 week, then replaces it by another one placed at a different site for a total of 3 weeks, followed by 1 week with no patch. The patches work by preventing ovulation, thickening the cervical mucus and suppressing endometrial growth.

Ortho-Evra is a square patch resembling a light-brown bandage. Each side is about 4.45 cm (1.75 inch) long. The patch is applied over dry skin on the buttocks, lower abdomen, upper outer arm or the upper body (front or back) but not on the breasts. The patch adheres well to the skin, allowing women to perform daily regular activities such as bathing, swimming, working and exercising without interruption even in warm, humid climates. It falls off in about 2% of cases.

It provides effectiveness and cycle control like those of OCs when used. The failure rate with typical use within the first year is 2 per 100 women and with perfect use 0.3 per 100 women (or 3 per 1,000).

The first patch should be applied within the first 5 days of menstruation. It should then be changed each week for 3 weeks, applying it each time to a new location. For the fourth week, no patch is worn, to allow for withdrawal bleeding. However, it may be used continuously, using a fourth patch in fourth week if the withdrawal bleeding is to be delayed.

Skin irritation or rash at the site of application is the most common side effect of Ortho-Evra. Other side effects are like those of COCs. The incidence of break through bleeding and spotting is low among users of Ortho-Evra patch, and further decreases with longer use.
**Vaccines**

In order to stabilize the present population and check further population explosion, particularly in developing countries like India, there appears to be tremendous need to develop an effective, reversible, long-lasting and easy to administer contraceptive method. Research is on to produce vaccines which can be manufactured at a relatively low cost, administered by paramedics, and have long lasting reversible contraceptive effects but with a selective effect on the reproductive chain limiting the risk of metabolic effects.

The contraceptive vaccines that are being extensively researched at present are:
- **Anti-human chorionic gonadotropin vaccine**
- **Anti-zona pellucida vaccine**
- **Anti-sperm vaccine**

**Promising Trials and Development**

*Transdermal contraceptive spray or gel:* The progestogen nestorone, appropriate for breastfeeding women, is being tried at (phase I clinical trial stage) as a spray-on approach for transferring a preset dose of fast-drying hormone on to the skin.

**Male Fertility Regulation**

The hormones that have been tried for male contraception are:
- **Androgens:** Testosterone enanathate 200 mg injections administered weekly; testosterone buciclate.
- **Progestogen:** DMPA
- **Antiandrogen and progestogen:** Cyproterone acetate.
- **Gonadotropin releasing hormone analogs:** Agonists; antagonists

Research is on in the field of producing biodegradable testosterone microcapsules and testosterone pellets, for the maintenance of sexual function.

In India, a multicentric phase III human clinical trial with an injectable contraceptive named RISUG (acronym for Reversible Inhibition of Sperm Under Guidance) is underway. RISUG is injected into the vas deferens, a single 60 mg injection of which can provide contraception for 10 years. A single dose is expected to cost ₹ 70/- with no side effects reported so far. Smaller doses of RISUG are also being tested for providing contraception for shorter periods, and possibly making it a reversible method of male contraception.

*Intra vas device:* Intra vas device (IVD), originally called Shug, is a device (plug) that is implanted in the vas deferens. Two plugs are implanted into each vas deferens. In animal studies, the IVD resulted in no sperm reaching the ejaculate, but after removal of the devices, all primates ejaculated normal numbers of sperm again. However, the method requires special technological skill like that of the ‘no-scalpel method’ of vasectomy. Wider trials are needed.

**Plant compound pills:** Attempts are being made to isolate newer isomers of gossypol and try their antifertility effects. The toxicity of these products will be keenly watched; however, the use of gossypol is being discouraged by some workers. Oral compound such as triptolide, extracted from the Chinese plant *T. wilfordii* is being investigated by the WHO for its antifertility effect.

**Beyond 2020**

- **Regulatory peptides**
- **Gene therapy**

Both regulatory peptides and gene therapy in relation to contraception are in their infancy, but hold great promise for the future.

**Male Vaccine**

Having failed to produce a safe, effective and reversible male contraceptive vaccine against hormones such as FSH and GnRH analogs, scientists are currently endeavoring to isolate, identify and produce antisperm surface antigens so as to develop a contraceptive vaccine which will hinder sperm-egg union without bad side effects. However, the development of such a method of contraception is not expected in the near future.

**CONCLUSION**

A recent International conference on the quality of care for family planning, reproductive health, and the three China National Comprehensive Programs (3 NCPs), held in Beijing, summed up the need for the “Program for Improving Quality of Contraceptive Care” project, where the participants reached a consensus to stress that:

- Informed choice and follow-up services are necessary
- Different contraceptive methods should be used at different ages
- Attention should always be paid to medical condition, lifestyle, and culture
- In addition to informed choice, all the other aspects of reproductive health care must be addressed. A specific example is the provision on the migrant population’s education about the prevention of STDs.

We, in India, can definitely learn from the tremendous success that China has achieved in controlling its population by proper planning and implementation of its family planning services, to hasten economic and social development.

Although it is almost impossible to cover all the areas of steroidal and nonsteroidal contraception in females and males in a single chapter, every attempt has been made to bring to light some of the existing methods and exciting new advances in the field of contraceptive technology. Newer molecules and drug delivery systems are on the anvil, some under research and others in phase II, III and IV clinical trials. We await the future of contraception with bated breath!!
REFERENCES

INTRODUCTION

Abortion care should be made available as close to people’s homes as possible and should be performed by the least specialized personnel who are adequately trained to perform it safely and well.\(^1\)

The benefits of this proposition are particularly relevant in a geographically large country like India, with its population of over a billion. In spite of having legalized Medical Termination of Pregnancy (MTP) over 3 decades ago, India still grapples with varied levels of facilities stretching unevenly over the subcontinent, to provide greater access to safe abortion. This presentation reviews the current status of abortion practice and outlines and summarizes possible solutions and directions for the future.

CURRENT STATUS OF ABORTIONS

More than 75 million women worldwide experience an unwanted pregnancy each year.\(^2\) Two-thirds of these women opt for induced abortions. Of these procedures, 20 million are deemed unsafe.\(^1\)

Approximately, 25% of the world’s population lives in countries where abortion is illegal without exception or is permitted only to save the life of a pregnant woman.\(^2\) While only 22% of the 190 countries in the world have laws allowing abortion on request, the Indian Medical Termination of Pregnancy Act with its acceptance of sociomedical indications rates amongst the most liberal.

Estimates of Abortion Prevalence

The reported worldwide abortion rate is around 35 per 1,000 women aged 15–44 years.\(^4\) It is estimated that 55,000 unsafe abortions take place everyday. Half of all women having illegal abortions live in Asia, 25% in Africa, 20% in Latin America and the remaining 5% in eastern Europe.\(^1\)

An estimated 6.7 million induced abortions take place each year in India. In contrast, national MTP records report approximately 0.6 million MTPs. This indicates a ratio of 10–11 illegal abortions for each MTP reported in national statistics.\(^1\)

This high ratio of illegal abortions may be attributed to a total lack of awareness regarding the legality of MTPs in India in the general population, paucity and inaccessibility of appropriate, recognized facilities and a tendency to seek services from easily approachable traditional birth attendants and quacks. Interestingly an ICMR survey on illegal abortion has highlighted a preference for qualified doctors and approved institutions. However, poor knowledge or inaccessibility of facilities, lack of courteous and compassionate interaction and a concern for secrecy deters clients from accessing public health facilities.\(^5\)

Ironically, a significant number of unreported MTPs are actually performed by qualified medical personnel, either because the well-equipped centers lack recognition or the accessory clinical documentation and paperwork is inadequate. These MTPs may be referred to as the safe illegal abortions, though in the eyes of the law their legal status is no different than any criminal abortion.

CHARACTERISTICS OF ABORTION SEEKER

The characteristic profile of women seeking abortion in India is of young, married women with at least 2 or more living children, who have failed to use contraception or in whom contraceptives have failed, and who do not want more children at all, or just at yet.\(^5\)
In marked contrast late abortions were more often sought in adolescent and unwanted pregnancies. A series of 2,055 second trimester MTPs represented 15% of all abortions over 10 years. While unmarried adolescents represented 5.5% of all MTPs, they accounted for 18.6% of second trimester MTPs. The MTP Act of 1971 has been beacon of social and medical legislation with far reaching positive benefits for the reproductive health of women. It is an empowering Act for the healthcare system and its beneficiaries, setting aside the application of the IPC in certain well-defined sociomedical situations.

Safe Abortion Services: Inadequate Availability

There exists great inequity in the availability of safe, legally recognized abortion services in India. This has led to a situation where only a tenth of an estimated 6.7 million abortions induced annually in India are being reported. This disparity exists at least in part due to the fact that there were just around 9,467 approved institutions for providing safe abortion services for the entire country in 1997. This problem of inadequate facilities is even more acute in the rural setting with only 1,800 out of over 20,000 primary health centers offering MTP facilities. This deficiency was attributed to the fact that the current overly medicalized requirements for conventional procedures demanded by the MTP Act and Rules are difficult to achieve and hence a hurdle to widespread availability of safe abortion.

Certification procedures for facilities were cumbersome and bureaucratic and have become the main hurdle to expanding safe abortion services through the private and NGO sectors. A FOGSI questionnaire on MTPs in clinical practice elicited 118 responses. While 28.8% centers reported easy recognition, 12.7% were recognized after delays from 1 year to 7 years, 44.1% reported difficulties in navigating the recognition process, while 11.9% of respondents were unaware of the need for center recognition. There was scope to simplify and streamline bureaucratic procedures by amending MTP rules and regulations. In what proved to be a stellar demonstration of government, professional organization and NGO partnership, the MTP Act was amended in 2002 and the rules were amended in 2003.

National Population Policy

A significant aspect of the National Population, 2000, was the serious thrust in establishing decentralized safe abortion services. It is proposed to achieve this by disseminating community level education about the availability of safe, legal abortion, increasing the geographic spread and enhancing affordability, adopting updated safe, easy and simple technologies, eliminating cumbersome registration of centers and establishment of additional training centers.

Amendments to the MTP Act and Rules

The amendments introduced in the Act in 2002 and in the rules in 2003, corrected longstanding discrepancies and addressed contemporary issues. The term lunatic was replaced by

LEGAL STATUS OF INDUCED ABORTIONS IN INDIA

Even today voluntarily “causing miscarriage” to a woman with child—other than in “good faith for the purpose of saving her life” is a crime under Section 312 of the Indian Penal Code (IPC), punishable by simple or rigorous imprisonment and/or fine.

Consequent sections (IPC Sections 313–316) relating to causing miscarriage without a pregnant woman’s consent or causing maternal death due to the procedure, are stricter, with punishments ranging from up to 10 years imprisonment and extending up to life imprisonment.

Legalization of Safe Abortion in India: Background Scenario

It was to stem the high maternal morbidity and mortality associated with illegal abortions that the Government of India set up the Shantilal Shah Committee, which after deliberating a wide range of evidence over 2 years recommended a broadening and rationalization of laws related to abortion in 1966.

Based on these, a MTP bill was introduced in the Rajya Sabha in 1969, referred to a Select Joint Committee Review and finally passed as the MTP Act in 1971.

The Medical Termination of Pregnancy Act, 1971

The MTP Act (Act No. 34 of 1971) has been defined in its opening lines as “An Act to provide for the termination of certain pregnancies by registered medical practitioners and for matters connected there with or incidental thereto.”

Legislated by Parliament on August 10, 1971, this central act was passed to extend to the whole of India except the State of Jammu and Kashmir and to be enforced across the country from 1st April 1972. In 1980, Jammu and Kashmir and Mizoram also adopted the MTP Act. However, it is still not applicable in Sikkim and Lakshadweep.

The purpose of this act is to define the situations and circumstances in which safe abortion could be legally performed and to empower medical practitioners and institutions delivering this service. The MTP Act, if adhered to completely, offers full protection to the medical practitioner from consequences of the IPC. However, this legal protection is only available, conditional to every requirement of the Act being fulfilled.

Certification procedures for facilities were cumbersome and bureaucratic and have become the main hurdle to expanding safe abortion services through the private and NGO sectors. A FOGSI questionnaire on MTPs in clinical practice elicited 118 responses. While 28.8% centers reported easy recognition, 12.7% were recognized after delays from 1 year to 7 years, 44.1% reported difficulties in navigating the recognition process, while 11.9% of respondents were unaware of the need for center recognition. There was scope to simplify and streamline bureaucratic procedures by amending MTP rules and regulations. In what proved to be a stellar demonstration of government, professional organization and NGO partnership, the MTP Act was amended in 2002 and the rules were amended in 2003.

National Population Policy

A significant aspect of the National Population, 2000, was the serious thrust in establishing decentralized safe abortion services. It is proposed to achieve this by disseminating community level education about the availability of safe, legal abortion, increasing the geographic spread and enhancing affordability, adopting updated safe, easy and simple technologies, eliminating cumbersome registration of centers and establishment of additional training centers.

Amendments to the MTP Act and Rules

The amendments introduced in the Act in 2002 and in the rules in 2003, corrected longstanding discrepancies and addressed contemporary issues. The term lunatic was replaced by
mentally ill person (person in need of treatment by reason of any mental disorder other than mental retardation). This is a more pragmatic dispensation as compared to the definition from the Indian Lunatic Act, 1912. To ease the registration of centers, the power to register centers was delegated to a district level committee constituted by the government with the CMO or DHO as the Chairperson with a directive to complete inspection within 2 months of submission of application. By differentiating first trimester terminations (gynecology/labor table, back-up for treating shock and facilities for transportation) from second trimester terminations (operation theater table and instruments for abdominal and gynecological surgery, anesthetic equipment), the requirements for early abortions are now easy to fulfill. Medical methods for termination of pregnancy not exceeding 7 weeks may now be prescribed by a registered medical practitioner having access to any registered center.

For the first time, the concept of regulation and punishment was introduced with in the Act with rigorous imprisonment for a term not less than 2 years but which may extend to 7 years for termination by a person not an RMP and termination in place other than defined by the rules.

**TECHNICAL NUANCES OF MEDICAL TERMINATION OF PREGNANCY**

**First Trimester MTPs**

When performed in early pregnancy by well-trained practitioners in adequate facilities, abortion has an excellent safety record.\(^\text{13}\)

**Surgical Methods**

**Vacuum Aspiration: The Gold Standard**

Early abortions are undoubtedly the safest, with a fourfold increase in complications when abortions are performed late.\(^\text{1}\)

The effectiveness of vacuum aspiration for early induced abortion at over 98% is well established in large series and widely acknowledged in clinical practice. The results of meta-analytical study comparing vacuum aspiration with sharp curettage clearly established the undisputed supremacy of vacuum aspiration. Complications such as bleeding and cervical injury were reported to be twofold and uterine perforation sixfold higher with conventional curettage than with vacuum aspiration.\(^\text{14}\) Scientific evidence now suggests that it is time to abandon conventional D&C for induced abortions and the traditional check curettage after suction evacuation, in favor of an exclusive manual or electric vacuum aspiration.

**Resurgence of Manual Vacuum Aspiration in Medical Literature**

Recent medical literature is replete with references testifying to an increasing application of manual vacuum aspiration (MVA) in the practice of induced abortion throughout the first trimester.

Edwards and Carson reported MVA use for early pregnancy termination with postoperative inspection of the villi and transvaginal ultrasound with a 99% success.\(^\text{15}\) Westfall et al. performed MVA up to 12 weeks in a primary care office setting in 1,769 cases. They reported a 99.6% success with only a few minor complications such as retained products and infection.\(^\text{16}\)

**FOGSI Ipas Multicentric Study**

A prospective multicentric study was conducted in 27 purposively selected centers in nine cities and towns across the country over 6 months in 2004 to assess the effectiveness of using the double valve syringe to perform MVA throughout the first trimester. Of the 1,686 MVA procedures reported 1,203 (71.3%) were for MTP and 36% of the MTPs were for pregnancies of over 8 weeks. Complete evacuation with MVA was possible in 99.5% of cases below 8 weeks and 98.2% of cases over 8 weeks gestation. Incomplete abortions and other complications were reported in 2.9% of cases. Most procedures irrespective of gestation period were completed in less than 15 minutes and over half the cases were successfully managed under local anesthesia and/or sedation. The use of check curettage did not decrease the rate of incomplete abortion.\(^\text{11}\)

The multicentric study demonstrated that even in rural life service delivery settings with their inherent variations in clinical practice, instrument handling, case selection criteria and comfort levels of service providers using the equipment, MVA is an effective procedure with a few complications and is being used safely throughout the first trimester of pregnancy. This evidence is even more significant in the light of amendments in the MTP rules in 2003 rationalizing requirements for first trimester MTP provision thus providing an excellent opportunity to expand access to safe abortion through the use of this technology.

A useful observation by the contributors was the potential for reuse of both the MVA syringe and cannulae after simple sterilization procedures. Most centers continue to utilize the original syringe after completing over 50–75 cases.

**Essential Basic Procedure**

The effectiveness, safety and simplicity of the MVA procedure has earned it an endorsement as an essential basic procedure at the first referral unit (FRU) level.\(^\text{17}\) It is now well-established that outpatient MVA under local anesthesia increases access to safe abortions, shortens wait, reduces risk of complications and costs and facilitates links between emergency and contraceptive services.\(^\text{18}\)

**Medical Methods**

With the availability of mifepristone-misoprostol in India since it was approved 6 months ago, there now exists a valid...
option to a surgical procedure. Pioneering studies involving this technique were undertaken in India by Krishna and Coyaji. An interesting study reported its use in rural Indian villages between 1995 and 1998. A total of 294 cases were studied with a 95.9% success. This proved the method to be feasible, safe and effective in varied settings. There is hence great promise of medical methods with MVA backup to promote widespread availability of safe abortions.

Medical abortion technologies have low failure rates, however, it is essential that providers of medical abortion to establish standing arrangements for backup with vacuum aspiration.

Second Trimester MTPs
While late abortions have traditionally been induced by numerous methods, practitioners in India probably have the largest experience of using extra-amniotic ethacridine lactate. Described as the most common and most widely accepted method with documented safety, the main disadvantage is a relatively prolonged induction-abortion interval. A number of combinations have been tested to overcome this. The most effective was the use of extra-amniotic ethacridine lactate with supplementary extra-amniotic 15-methyl PGF₂α (250 g after 6 hours). A study of 315 cases reported an increase in successful termination from 92% to 98% and a reduction in induction-abortion interval from 35 hours to 19 hours with prostaglandin supplementation.

While still resorted to occasionally, effective non-surgical methods have made hysterotomy obsolete and discredited as a primary procedure. There remains a marginal role for aspirotomy in early second trimester during the gray zone when medical methods are not quite effective. These procedures are best performed under USG guidance, to enhance safety.

ABORTION RELATED COMPLICATIONS
Between 1 and 5 of every 10 women undergoing unsafe abortions, need medical care for complications such as sepsis, hemorrhage and trauma. Unsafe abortions result in an estimated 50,000 to 100,000 maternal deaths and many more injuries each year. About a fifth of this burden is borne by India.

TRAINING INTERVENTIONS
The most important strategy to make abortions safe is to increase the number of trained persons who can do the job. In 1997, there were only 163 designated MTP training centers in the country, with a capacity to train around 20 doctors percentage each year, since every trainee had to have practical experience of at least 25 MTPs.

Expansion of the pool of trained abortion providers to include midlevel clinicians has been suggested as an additional way to address the provider shortage.

For any successful mass introduction of safe abortion techniques, it is necessary to enhance training capacities by involving peripheral institutions and nongovernmental organizations besides the teaching hospitals.

Manual Vacuum Aspiration at Primary Health Centers: Pilot Project
A partnership between the Ministry of Health and Family Welfare, Government of India (GOI), State Governments, FOGSI and the World Health Organization (WHO) has been evolved to enhance the delivery of safe abortion services at the district and primary health care (PHC) level in chosen districts. This is to be achieved by training medical officers in government service at the districts and PHCs to decentralize early safe abortion services by introducing MVA services at the grass roots level in the health care system.

Safe Abortions Save Lives
Unsafe abortion endangers health in the developing world and merits the same dispassionate, scientific approach to solutions as do other threats to public health. There is an ample evidence that allowing abortion on liberal grounds reduces maternal morbidity and mortality. India has successfully overcome legal and ethical challenges to induced abortion services, by having in place landmark legislation. Now remains the process of decentralizing and disseminating abortion through establishment of centers throughout the country and training available staff to deliver safe abortion services.

VISION FOR THE FUTURE
That every woman should have access to high quality comprehensive reproductive health services and no woman, even in the remotest corner of rural India, should have to die a preventable death as a result of an unsafe abortion and that every woman must have the right to choose and access safe abortion services with ease and dignity.

REFERENCES
INTRODUCTION

Since the time Medical Termination of Pregnancy (MTP) Act, has been passed in India in 1972, this procedure of termination of an unwanted pregnancy has gone through extensive clinical trials. Various methods have been tried and today some old methods have been replaced by newer and safer techniques. Today more emphasis is on medical methods than surgical methods, especially in the western countries to reduce the cost of hospitalization and to reduce the risk of anesthesia and surgical trauma. However, in our country due to high cost, many clinicians prefer surgical methods for 1st trimester termination, as they are quicker, safer and are considered as “one time procedure”.

As far as methods for 2nd trimester terminations are concerned the search is still on, for an ideal method. The method of choice for 2nd trimester termination today, is combination of extra-amniotic instillation of ethacridine lactate and newer prostaglandins (PGs). The intra-amniotic instillation of hypertonic saline is given up, as it causes severe complications like hypernatremia and disseminated intravascular coagulation (DIC), leading to death. Once again there is revival of “Menstrual regulation” (MR), currently known as “Manual vacuum aspiration” (MVA), specially in developing countries with availability of better MR syringes. This MVA seems to be very promising especially in rural and remote areas where electric power supply is either inadequate or erratic. Abortion is an impressively safe procedure in countries where it is legal, accessible and performed under modern medical conditions. The overall abortion related mortality rate among developed countries is less than 1/100,000 procedures. Reports published from North America and Scandinavia, consistently indicate complication rates for 1st trimester abortion of less than 10/100 operations.1

In a United States (US) report of 170,000 1st trimester surgical abortions performed in low risk women by experienced providers, complication rates requiring hospitalization was 0.71/1,000 cases and minor complication rate was 8.46/1,000 cases.2

In contrast, mortality and morbidity from unsafe abortion persist as major problem in most of the developing world. The World Health Organization (WHO) estimates between 50,000 and 100,000, women die annually as a result of illegal abortion with morality rate of 250–500 deaths/100,000 procedures.

Common complications include infection, hemorrhage and uterine injury. In India, in spite of liberalization of abortion since 1972, even after 30 years many more abortions are carried out illegally and under unsafe conditions, according to Chhabra and Nuna.3

In India, illegal abortion today outnumber the legal procedures, by a ratio of 11 is to 12 with a high maternal mortality of 15%. According to WHO, over 20,000 Indian women die annually due to unsafe abortions.4

According to Ford Foundation Study (1995),5 the number of illegal abortions has risen dramatically, from 6.5 million in 1971 to 7.5 million in 1981, to 8.5 million in 1991.

Factors that increase the risk of abortion-related complications include older age, multiparity and advancing gestational age,6 the methods of abortion, skill of the surgeon, accessibility and quality of medical facilities to treat complications and added procedures like tubectomy or
insertion of intrauterine contraceptive devices (IUCDs) also increase the complication rates.

In a large prospective study of 2nd trimester abortion complications, dilatation and evacuation (D & E) was safer than instillation procedures using PG or hypertonic saline.\textsuperscript{7}

According to legal abortion mortality data collected by Centers for Disease Control and Prevention (CDC), US from 1972 to 1987 the number of deaths per 100,000 abortions was 0.5 for 1st trimester vacuum curettage procedures, 3.7 for surgical dilatation and evacuation (D & E), 7.1 for instillation procedures and 51.6 for hysterotomy/hysterectomy.\textsuperscript{8}

Tyler\textsuperscript{9} calculated that between 16 weeks and 20 weeks gestations the risk of death is 25 times greater than before 8 weeks gestation. Similarly, mortality increases during the 2nd trimester on an average of 20.1 per week, for major complications.\textsuperscript{10}

Complications can be broadly divided as methods:
- Complications due to surgical methods
- Complications due to medical methods.

**COMPICATIONS DUE TO SURGICAL METHODS (TABLE 1)**

The complications can be divided into:
- Early (within 1 month of abortion)
- Late (occurring after 1 month of abortion).

The “early” complications are further subdivided into “immediate” and “occurring not during the procedure but within 1 month”. If the procedure is done under anesthesia there can be complications due to anesthesia also and will depend upon the type of anesthesia used.

| Uterine perforation               | Immediate but may not be recognized until later | Varies from asymptomatic to very serious:  
|                                   |                         | potentially life-threatening           |
| Anaphylaxis                       | Immediate               | Potentially life-threatening            |
| Seizure                           | Immediate               | May be serious or not serious depending on etiology and seizure type |
| Embolism                          | Immediate               | Potentially life-threatening            |
| Cervical laceration               | Early                   | Usually not serious                    |
| Disseminated intravascular coagulation | Early            | Deep lacerations or cervical fracture can be potentially life-threatening |
| Uterine atony                     | Early                   | Potentially very serious                |
| Hematometra                       | Early or delayed        | Depends on amount of blood loss        |
| Failed abortion                   | Early or delayed        | Usually not serious                    |
| Ectopic pregnancy                 | Early of delayed        | Not serious if pregnancy is intact     |
| Endometritis                      | Delayed                 | Serious: potentially life-threatening  |
| Incomplete abortion               | Delayed                 | Usually not serious if treated promptly |
| Postabortal triad                 | Delayed                 | Usually not serious                    |
| Septic incomplete abortion        | Delayed                 | Serious: potentially life-threatening  |

**Complications According to the Methods of Abortion**

**Menstrual Regulation\textsuperscript{11}**

As the procedure is performed before pregnancy is confirmed by pregnancy test, the procedure is performed unnecessarily on 27–59% of cases.

As these patients were not pregnant, this misdiagnosis of pregnancy can be reduced by using sensitive pregnancy test, using beta human chorionic gonadotropin ($\beta$hCG) specific assays, using ultrasonography and examination of aspirated material.

- **Failure abortion:** This is also common complication when MRD is performed very early as gestation sac can be completely missed, if situated in cornual region. The incidence reported is 3–12%. This can be reduced by doing MR under ultrasound control. Also all the products should be carefully examined and patient should be called for follow-up after 1 month, so if pregnancy is continuing it can be diagnosed and the procedure repeated.

- **Incomplete abortion:** This is also very common specially, if the surgeon is inexperienced or MR surgical procedure is not properly performed. The incidence varies from 5% to 30%.

- **Hemorrhage**

- **Trauma:** Cervical trauma or uterine perforation incidence are very low as plastic cannula is used.

Fracture of the tip of the cannula a very rare but can occur, if disposable cannula is used. Dilation and curettage will be required to remove the tip of the cannula.
Complications and Sequelae of Medical Termination of Pregnancy

54

CHAPTER

Complications due to Dilatation and Suction Evaluation

Early Complications Occur during Operations

- Incomplete evaluation
- Trauma
  - Trauma to cervix: Cervical laceration or tear could occur. The injury to cervix can be reduced by using a traumatic tenaculum or priming the cervix with either PGs. Cervical tears near internal os, can cause severe hemorrhage and must be sutured immediately.
  - Uterine perforation (Fig. 1): Uterine perforations are common in cases of multiparity or advanced pregnancy more than 14 weeks gestation or when uterus is previously scarred like with previous cesarean sections, metroplasty, etc. Uterine perforation is suspected when instruments pass further than expected without any resistance or when bleeding is excessive or when bowel or omentum is seen outside the cervix.
  - Injury to surrounding structures like urinary bladder intestines, omentum, etc. specially if there is uterine perforation with sharp curette or aspiration cannula.
- Hemorrhage: Uterine hemorrhage associated with abortion indicates cervical laceration, perforation, retained pregnancy tissue, uterine atony, placental abnormality or coagulopathy. Definition of hemorrhage varied in different studies from blood loss of 250 cc or 500 cc more to patient requiring hospitalization or blood transfusion. The incidence varies from 0.07% with gestational age less than 13 weeks to 12% when gestation age is 13–15 weeks. Advances in operative technique and prophylactic use of intramuscular (IM) injection, PG half hour prior to procedure reduces the incidence of hemorrhage.
- Infection.

Role of Ultrasound

Ultrasound plays a very important role to MTP in knowing the exact size of the uterus, diagnosis of fibroid with pregnancy, diagnosis of twins and multiple pregnancy or vesicular mole and also diagnosis of uterine malformation. Ultrasound also plays important role during surgical evacuation specially in cases of extremely obese patients, bulky uterus pregnancy and when patient has undergone previous cesarean sections. Ultrasound helps in prevention of perforation and ensures complete evacuation thus, reduces chances of retained product and hemorrhage.

The management of uterine perforation depends upon amount of bleeding, types of instrument that caused perforation and, whether intestine or bladder is injured or not. Immediate laparoscopy is performed to assess the size of perforation and injury to other organs. If perforation is small and there is no active bleeding, patient is observed for 24 hours and discharged, if stable but if perforation is large and there is excessive bleeding or bowel or bladder is injured, immediate laparotomy is carried out. Perforation bladder injury that is also properly sutured is sometimes, necessary as a life-saving procedure.

Aspirotomy

Aspirotomy is a combination of section, aspiration and embryotomy carried out under paracervical block injection of adrenaline and saline in lower uterine segment to reduce the blood loss. It is also known as D & E procedure. It is normally carried out when uterine size is more than 14 weeks and up to 20 weeks of pregnancy. It is a good method for 2nd trimester termination as its procedure is quick and complete and patient can go home in 2–3 hours. It is very popular in western countries specially Europe as cost of anesthesia is used by many obstetricians but requires proper training and use if aspirotomy forceps. The method was tried at MR Wadia Maternity Hospital by Dr MR Parikh and his team. They have performed more than 500 aspirotomy procedures, without major complications.12,13

Complications

These include cervical trauma, laceration uterine perforation and incomplete abortion specially retention of bony fragment
as pregnancy is advanced, there can be severe hemorrhage as uterus will be larger. The aspirotomy should be performed by an experienced gynecologist and must always be done in a good set-up with facility for laparotomy control to ensure the complete evacuation and to prevent perforation.

**Hysterotomy**

It is rarely done as a primary procedure for abortion but is carried out for failed 2nd trimester termination, especially when instillation procedures are used. It is a major operation which requires anesthesia and proper hospital facilities.

**Complications**

It is an invoice procedure. Hemorrhage can occur if uterine incision is not properly sutured.

*Infection:* Normally occurs due to failed termination and prolonged induction abortion interval.

**Hysterectomy**

Rarely done for 2nd trimester termination. It is selectively done in cases of failed terminations, with severe sepsis or hemorrhage. Sometimes, it is done as a primary procedure in multiparous patient with gynecological problems like multiple fibroids and dysfunctional uterine bleeding (DUB) or pregnancy with carcinoma cervix.

**Complications**

It is a major surgical procedure and carries, with if the high incidence of morbidity and mortality. Hemorrhage can occur due to increased vascularity. Maternal mortality can occur due to severe hemorrhage or due to anesthesia complications.

**Delayed Complications due to Surgical Methods**

- Retained products of conception or incomplete evacuation. This is one of the most common complications seen in about 5% of suction evacuation. It can lead to hemorrhage and infection if not treated. The diagnosis is made with help of ultrasound, which shows retained products of conception. Treatment is readmission, report dilatation and evacuation. The incidence of incomplete evacuation can be reduced by doing “check curettage” or by doing MTP under ultrasound control, especially with early abortions or less than 6 weeks and late abortions after 12 weeks.
- *Pelvic infection:* Worldwide rates of infection after 1st trimester termination, varies from 0.1% to 4.7%. It is usually due to pre-existing pelvic infections either due to chlamydial infection, gonorrhea, bacterial vaginoses and the rare but extremely serious infections such as *Clostridium perfringens* and synergistic necrotizing infections. Sepsis, if not controlled can lead to septic shock and acute respiratory distress syndrome (ARDS). It can also be due to incomplete evacuation or if proper aseptic precautions are not used. The incidence of infection can be reduced by using all aseptic precautions, complete evacuation of the uterus and use of prophylactic antibiotics.
  - *Amniotic fluid embolism:* It is very rare but fatal occurs in 1/10,000–1/80,000 pregnancies.
  - *Pulmonary embolism:* A retrospective CDC study described 10 cases of fatal pulmonary embolism for the period, 1972–75 occurring 2–50 days after induced abortion. Patient had one or more risk factor like obesity, hypertension and recent use of oral contraceptives or family history of embolism.

**Complications due to Anesthesia in Surgical Procedure**

- Vasovagal reaction
- Anaphylaxis
- Asthmatic reactions
- Seizures
- Bronchospasm
- Cardiac arrest.

**COMPLICATIONS DUE TO MEDICAL METHODS OF TERMINATION**

**Medical Methods for First Trimester**

The common method used is combination of mifepristone (RU-486) and misoprostol. Mifepristone 600 mg followed by 36–48 hours later, with 1 mg of gemeprost vaginal pessary or misoprostol tab 200 µg.

**Complications**

- Headache, malaise, skin rash.
- Adrenal failure
- *Bleeding:* Irregular bleeding normally occurs from 1 day to 10 days. Patient must be called for follow-up and if bleeding is severe patient requires admission and blood transfusion, the reported incidence is 1 in 2,000 cases—0.85%.
- *Failed attempted abortion:* Seen in about 1–2% of cases of patients with pregnancy less than 7 weeks. Patients are called for follow-up and advised to undergo surgical evacuation because of potential teratogenic effect on the fetus. PGs cause constriction defects in distal limbs.
- Next menstruation may be delayed by 10–15 days.

Intramuscular methotrexate and intravaginal misoprostol is also used as a medical method of abortion. Incidence of failed abortion varies from 3% up to 49 days of gestation.
and less than 12% at 50–56 days of gestation.\textsuperscript{15} However, as methotrexate is toxic drug, it is not widely used. If pregnancy continues patient is advised to undergo suction evacuation because of the potential teratogenic effect on the fetus.

Complications of Second Trimester Abortions

1. **Intra-amniotic instillation of hypertonic saline 20% NaCl 200 mc**: This method is associated with some major complications including maternal mortality and therefore, not used in big cities where prostaglandins are available. However, in smaller places and in some centers in big cities it is still used as prostaglandins are expensive.

   **Immediate complications**
   - **Incomplete abortion requiring curettage**: For about 3.3–13% patients will have incomplete abortion and will require D & E under anesthesia.
   - **Failed abortion**: About 1–3% will have failed abortion after 48 hours cut-off point and will require reinstallation.
   - **Hemorrhage**: This could be due to retained placenta, atomy of the uterus or due to DIC. The incidence of bleeding, following saline instillation is about 16\% (Tietze and Lewit).\textsuperscript{16}
   - **Hypernatremia**: This occurs due to accidental injection of saline into blood vessel. This leads to immediate cardiovascular collapse or cerebral edema followed by convulsions, hypoxia and failure of one of the vital organs. However, the incidence is very low 1:4,000.\textsuperscript{17}
   - **Disseminated intravascular coagulation**: This is also a serious complication leading to severe bleeding and the incidence with hypertonic saline is 658/100,000 abortions.\textsuperscript{18}
   - **Uterine wall necrosis**: This occurs due to accidental injection of hypertonic saline into uterine wall. This is also a serious complication and can lead to death.
   - **Maternal mortality rate varies from 0 to 8/1,000 instillations. The causes are hypernatremia, endotoxic shock, DIC and cerebral hemorrhage.**

2. **Intra-amniotic instillation of 40% urea**: It is an inert substance and therefore, no harm occurs even, if accidentally injected into vein or uterine muscle. Therefore, many prefer this method over hypertonic saline instillation.

   **Complications**
   - **Failed abortion**: Success rate of the method is 86%. Retained placenta and incomplete abortion with urea prostaglandin F2 (PGF2) the reported incidence is 35–46\%.\textsuperscript{19}
   - **Hemorrhage**: Rare with urea, but can occur sometimes, but severity is less than saline.
   - **Urea**: is hepatotoxic and toxic to kidneys therefore, cannot be used for patients with renal or liver disease.

   **Extra-amniotic Instillation of Ethacridine Lactate**

   This is the method of choice for 2nd trimester abortion in India, in majority of centers, as it is safe, cheap and ethacridine is easily available.

   **Complications**
   - **Failure of abortion**: This is common and sometimes abortion does not occur even after 72 hours. This can be reduced by combined with PGs.
   - **Incomplete abortion**: The reported incidence is about 10\%. Dilatation and evacuation is done to complete the abortion.
   - **Renal damage and death**: If excess of ethacridine is injected, i.e. more than 50 mL, it can lead to renal toxicity and death. However, this is a very rare and so far only 1 death is reported from Gujarat.

   Pytel et al.\textsuperscript{20} from Soviet Union have reported 5 cases of acute renal failure following large volume of ethacridine lactate more than 500–700 mL. These patients were treated with hemodialysis.

   **Prostaglandins**

   They are used quite frequently nowadays in India as they are easily available and are effective in producing abortion. They are used either alone or as combination with urea or ethacridine lactate. They can be given by various routes intra-amniotic instillation, intravenous (IV), IM and now newer analogs can be given vaginally, intracervical or even orally.

   **Complications**
   - Side effects like gastrointestinal disturbances are very common—vomiting, diarrhea. Sometimes, it can be very severe and patient needs IV fluids infusion.
   - **Cervical tears**: Occur in many cases, specially bucket handle type. The incidence of cervical laceration, reported is 1%.
   - **Transverse rupture of the posterior uterine wall**: This is a serious complication. The rupture occurs because of the tetanic type of contractions with PGs.
   - **Hemorrhage**: Either due to lacerations or tear of the cervix or rupture or due to retained products.
   - **Convulsions**: Can occur sometimes.
   - **Incomplete abortion**: Sometimes placental tissue is retained. This requires dilatation and curettage.
   - **Expulsion of the live fetus**.
   - **Sudden maternal death**: Cases of sudden maternal deaths have been reported with use of sulprostone. Also when used in combination with RU486, three women developed myocardial infarction. Therefore, sulprostone is no longer used for termination of pregnancy. It is also advised that PGs should not be used in women who are obese, heavy smokers and have history of hypertension.
SECONDARY INFERTILITY:

Due to infection following MTP, leading to PID and tubal blockage. Chlamydia organism is the most common cause of secondary infertility following abortion. Examination for chlamydia is now routine in most hospital and clinics and if necessary patient is treated before abortion is carried out.

INCOMPETENT OS LEADING TO REPEATED ABORTIONS OR PRETERM DELIVERIES:

Occurs either following repeated MTPs or sometimes with aspirotomy procedure.

ASHERMANN’S SYNDROME:

This is due to vigorous curettage or postabortal infection, this complication is seen rarely if proper care is taken while doing MTP.

RH ISOIMMUNIZATION:

Usually occurs in a Rh negative patient if Rh anti D immunoglobulin injection is not given. It is advisable that prior to all MTPs whether 1st trimester or 2nd trimester, blood grouping and Rh typing should be done to avoid occurrence of Rh isoimmunization.

PSYCHOLOGIC SEQUELAE:

Seen in women with a previous history of psychiatric disorder or when MTP is done against the desire of the women. It is also seen in Muslim and Christian as their depression is psychologic.

ECTOPIC PREGNANCY FOLLOWING PID.

REFERENCES

INTRODUCTION
Contraceptive methods today are very safe and effective. However, we remain decades away from a perfect method of contraceptions for either men or women. Because reversible contraceptive methods are not perfect, sterilization is now the most commonly used method of contraception worldwide.

Vasectomy accounts for only a small percentage of sterilization procedures in developing countries except in India and China, worldwide, the ratio of female to male sterilization is 3 to 1.

History
James Blundell proposed in 1823, in lectures at Guy’s Hospital in London, that tubectomy should be performed at lower segment cesarean section (LSCS) to avoid repeat LSCS.

Madlener procedure, was the first technique devised in 1910, since it was associated with many failures, it was not popular.

Ralph Pomeroy described the technique in 1929.

Laparoscopic method was introduced in 1970s. When the risk of pregnancy from the contraceptive failure is taken onto account, sterilization is the safest of all contraception methods.

Vasectomy
Surgical sterilization of male: Vasectomy remains the most reliable, safe and cost-effective method of contraception. Failure rates are comparable with that of female tubal ligation. With improvement in vasectomy technique like no-scalpel technique, nonsurgical technique for vasectomy may become more acceptable.

Eligibility Criteria
The eligibility criteria are shown in Table 1.

Counseling
After selecting appropriate case for vasectomy, surgeon should provide information to the patient regarding permanence of the procedure, he should be reaffirmed that there will be no effect on masculinity, sexual activity and also has no demonstrable long-term deleterious effects.

Table 1: World Health Organization medical eligibility criteria for male sterilization

- **Contraindications:**
  - No permanent contraindication
- **Delay:** Procedure should be delayed until the condition has been successfully treated or no longer exists.
  - Intra-scrotal mass
  - Filariasis; elephantiasis
  - Signs/symptoms of STD
  - Infection of the operative area
  - Acute systemic infections
- **Refer/special precautions:** The procedure should be performed only in a facility well equipped and staffed to handle any potential difficulties or complications or it may be postponed.
  - Previous scrotal injury
  - Large varicocele
  - Large hydrocele
  - Inguinal hernia
  - Coagulation disorders
  - Previous surgery for cryptorchidism

*Abbreviation: STD, sexually transmitted disease*
CHAPTER

Permanent Methods of Sterilization

Technique

**Conventional Vasectomy**

It is done under aseptic precautions in the theater setup. Local anesthesia is usually used. Lignocaine 2% is injected into the area of incision at the junction of the upper third and middle third of median raphe to raise a 2 cm wheal over the vas. Vas deferens is fixed with fingers and lignocaine is injected into perivasal tissues. The skin and muscles overlying the vas are incised to about 1 cm transversely. The vas is grasped and isolated by incising longitudinally on the overlying sheath to expose the vas. The exposed vas is occluded and a segment of 2–3 cm is resected. The same procedure is performed on the other side. Incisions are closed.

**No-scalpel Technique**

Introduced in China, a simple no-scalpel technique reaches the vas through a puncture in the scrotum, rather than through a scalpel incision. Special instruments required for this procedure are—a vas deferens dissecting forceps and extra cutaneous fine vas fixing clamp. This procedure is done under local anesthesia with aseptic precautions. The vas is grasped with a ringed clamp, applied extra cutaneously to hold the vas in place. A puncture is made over the vas using the dissecting forceps. The forceps is then stretched and vas is lifted up. Vas is occluded as with other techniques. The puncture site needs no closure. This procedure also called “minimally invasive no scalpel” (MINS) vasectomy is less painful; less infection, less postoperative discomfort and takes less time compared to conventional vasectomy. This small variation reduces the chance of bleeding. However, MINS needs good practical training of doctor.

**Alternative**

Nonsurgical technique for vasectomy involves the injection of a polyurethane elastomer plug into vas via percutaneous puncture. Injection of silicon rubber has also been investigated. Other surgical alternative include, use of occlusive devices like plugs, clips, valves, etc.

Another variation is the open ended vasectomy, in which only the abdominal end of the severed vas is coagulated, while the testicular end is left open. This is associated with less chance of epididymitis.

**Postoperative Advice**

Unless warranted there is no need for antibiotics. Analgesics for pain can be advised for 2–3 days. Patient should be advised to avoid strenuous exercise for 2 days and cycling for 1 week. Scrotal support will reduce discomfort. Wound should be cleaned with soap water daily. Contraceptive measures should be advised for 3 months or 20 ejaculations which ever comes first. Protected coitus may be started 3 days following surgery.

**Efficacy**

Vasectomy is very effective method of contraception. Many of the failures are due to lack of precautions before semen becomes sperm-free. Technical failure may be due to spontaneous recanalization of vas, division of wrong structure, duplication of vas. Failure rate is 0.15 pregnancies/100 men in the 1st year after procedure.

**Complications**

Common minor short-term complications of surgery are:
- Pain in the scrotum
- Swelling and bruising
- Discomfort for 2–3 days.

These are often related to degree of patient’s apprehension. Significant pain is experienced in 1% of patients and may be associated with hematoma.

Bleeding, infections at incision site or inside the incision are uncommon complications. Clinical infection is noted in 1%. Rarely, abscess formation may require drainage.

Small hematomas or subcutaneous ecchymosis develops in few patients. They usually resolve within 1–2 weeks. Hematoma large enough requiring drainage may develop in less than 1% of patients.

Sperm granuloma may present in up to 1–3% of vasectomies. They may account for some vasectomy failures. They are painful and on occasion require excision.

Antisperm antibodies are formed in 40% of vasectomized patients. This phenomenon has been associated with failure of reversal.

Postvasectomy pain syndrome or chronic testicular pain is described but poorly understood.

Vasectomized men are not more likely to develop cancer, heart disease or other illness.

**Reversal**

Vasectomy is amenable to reversal by vasovasostomy. Patency rates of 80% can be achieved. However, pregnancy rates are lower than 5%.

The longer the interval since the vasectomy, the poorer the chance of reversal.

**Female Sterilization**

For couples desiring no more fertility this is one of the most effective and the best methods of contraception. Female sterilization is a permanent method of sterilization, a procedure which involves ligation with or without resection or blocking of both fallopian tubes.
It comprises around 94% of total number of voluntary sterilization in India.

**Selection of Cases**

Medical eligibility criteria were laid down by World Health Organization (WHO) in 1996.

- **Contraindication:** No permanent contraindication
- **Delay the procedure:** Delay the procedure till the underlying medical condition is treated and resolved. Temporary methods should be provided till then.
- Known or suspected pregnancy
- Active pelvic infection, peritonitis
- Pelvic inflammatory disease (PID) within 3 months
- Acute systemic infection
- Acute liver or gallbladder disease
- Current cerebrovascular
  - Postpartum, 7–42 days
  - Sexually transmitted diseases (STDs) infection
  - Severe anemia (< 7 g/dL)
  - Current, acquired immunodeficiency syndrome (AIDS) related illness
  - Unexplained vaginal bleeding suggestive of serious condition
- Any other temporary operative risk
- Any psychiatric condition that may impair decision making
- **Following pregnancy conditions:**
  - Puerperal sepsis
  - Premature rupture of membrane (PROM) more than or equal to 24 hours
  - Pregnancy with persistent hypertension
  - Postpartum psychosis
  - Severe trauma to genital tract
  - Recent septic abortion
  - Severe postabortal hemorrhage
  - Unhealthy newborn/stillbirth
- Special conditions need referral to a center where an experienced surgeon can perform in a setting equipped for general anesthesia (GA).

- Conditions that increase surgical difficulties:
  - Past cardiovascular disease
  - Chronic respiratory problems
  - Hyperthyroidism
  - Diabetes with vascular disease
  - Complicated valvar
  - Heart disease
  - Moderate anemia
  - Severe chronic liver disease
- Cautions mean procedure can be performed in a routine setting but with extra preparation with precautions depending on the condition:
  - Mild raise of blood pressure (BP) (140/90–159/99 mm Hg)
  - Past stroke or heart disease due to blocked arteries
  - Valvular heart disease without complications
  - Epilepsy on treatment
  - Diabetes without vascular disease
  - Hypothyroidism
  - Sickle cell anemia
  - Kidney disease
  - Obesity
  - Lack of nutrition.

Female sterilizations are mainly performed by two different types of procedures, namely:
1. Tubal ligation
2. Laparoscopic sterilization.

**Timing of Sterilization**

Sterilization can be performed:
- At the time of cesarean section
- Puerperal sterilization that is shortly after delivery in early puerperium. During this period, sterilization is technically easy as tubes can be approached through a small incision. This should be ideally done within 48 hours following delivery, but not beyond 7 days.
- Interval sterilization: Interval sterilization is done any time in nonpregnant women or 6 weeks after delivery. Tubal ligation should be done within 7–10 days of menstruation.
- Postabortal sterilization is done following induced abortion or after evacuating incomplete abortion.

**Counseling**

The following features of the sterilization procedure must be explained to the patient according to the Government of India, Family Welfare:
- It is a safe and simple procedure
- It is a permanent procedure for preventing future pregnancies
- It is a surgical procedure that has a small risk of complications requiring further treatment
- It does not affect sexual pleasure, ability or performance
- It will not affect the patient’s strength or his ability to perform normal day-to-day functions
- It has a small chance of failure, even if performed under optimum circumstances
- After vasectomy, it is necessary to use a back-up contraceptive method, either for 20 ejaculations or for a period of 3 months.
- Sterilization does not protect against STD/AIDS
- Patient must be told that a reversal of this surgery is possible, but the reversal involves a major surgery and its success cannot be guaranteed.

**Consent**

The written consent of spouse is not required for sterilization.
Preoperative Evaluation
Proper consent of the women should be obtained. The work up also includes careful history and physical gynecological examination. Pregnancy should be excluded at the time of sterilization.

SURGICAL APPROACH

Minilaparotomy for Tubal Ligation
Minilaparotomy approach for tubal ligation can be used in the interval, postabortal or postpartum period. In postpartum minilaparotomy, abdomen is opened by a 2 cm subumbilical incision 2 cm below the fundus.

Three centimeter midline transverse suprapubic incision 2.5 cm above the symphysis pubis. A uterine manipulator is placed just before surgery and is used to bring the uterus towards the incision. Trendelenburg’s position can be used to enhance exposure.

In either situations, the tube is identified first by the fimbrial end, and then mid portion of the tube is grasped with Babcock’s forceps and elevated through the abdominal incision. Tubal ligation is done by one of the following methods:

- **Pomeroy technique:** A loop is formed 2 cm lateral to fundus. Avoiding blood vessels, a round-bodied needle with no. 0 plain catgut is passed through mesosalpinx. The base of the loop is tied, leaving 2 cm of loop above the tie. 1.5 cm of loop is removed. The rationale of this procedure is based on prompt absorption of the ligature and subsequent separation of several tubal ends. Failure rate is 1/400 procedure.

- **Parkland technique:** This was designed to avoid the initial intimate approximation of the cut ends of the tube. After identifying the tubes, it is doubly ligated 2.5 cm apart with no. 0 chromic catgut and the intervening tube excised. Failure rate is 1/400 procedures.

- **Madlener procedure:** The Madlener procedure is similar to Pomeroy operation except that knuckle of the tube is crushed and ligated with nonabsorbable suture but not resected. Failure is about 7%.

- **Fimbriectomy:** Recommended by Kroener involves removal of all of the distal tube. This has a high failure rate of 2%. Other techniques not commonly used are Irving technique, Uchida technique.

Laparoscopic Sterilization
Because laparoscopy permits direct visualization and manipulation of the abdominal and pelvic organs with minimal abdominal discomfort, it offers many advantages.

- Surgeon has an opportunity to inspect the pelvic and abdominal organs for abnormalities.
- However, laparoscopic sterilization is not without disadvantages, which includes the need of expensive fragile costly equipment. Special training is required for the personnel. Finally, the risks inherent to procedure like inadvertent bowel or vessel injury are there.

Laparoscopic sterilization can be achieved by:

- **Electrocoagulation:** Unipolar method of sterilization creates a dense area of current, under the grasping forceps of the unipolar electrode. Isthmic pole of the tube is grasped and elevated away from the surrounding structures and the electrical energy applied until the tissue branches swells and then collapses. This procedure is repeated till 2–3 cm of tube has been coagulated. However, there is increased risk of ectopic pregnancy due to fistula formation. In bipolar method, current density is more at the point of forceps contact with tissues as current leaves the body via the same forceps. So more applications of grasping forceps are necessary to coagulate the same length of tube than with unipolar coagulation. Bipolar cautery is safer than unipolar. However, both are associated with thermal bowel injury.

- **Clips:** Two types of clips are widely used are:
  1. The spring loaded clip (Hulka-Clemens clip)
  2. Silicone—Titanium clip (Filshie clip).

  Filshie clip made of titanium lined with silicone is locked over the tube using a special instrument. Upper jaw latches under a hook in the lower jaw. Only 4 mm of tube is destroyed, providing good chance of recanalization. Hulka clip made of lexan has two jaws held together by a stainless steel spring. This should be applied at a 90° angle to include some mesosalpinx at the proximal isthmus of tube.

- **Rings:** Fallope ring, most popularly used in India at present is made of nonreactive silastic rubber band. Application needs a specially designed endoscopic applicator. A knuckle of tube is grasped and silastic ring is realized into 2.5 cm loop of tube. After devascularization, this portion of tube becomes anoxic and resorbs over time. Apart from included tube very little destruction is caused to the remaining tube.

  Failure rates are about 1% after 2 years. Mesosalpingeal bleeding is most common complication of silastic ring application. Occasionally, ring may be placed on structures other than tube, e.g. round ligament, mesosalpingeal folds leading to failure.

COMPLICATIONS

Common Intraoperative Complications

- Vasovagal shock
- Respiratory depression/arrest
- Cardiac arrest
• Bleeding from mesosalpinx
• Injury to urinary bladder
• Injury to intra-abdominal viscera
• Uterine perforation
• Reaction to local anesthesia.

Immediate Postoperative Complications
• Wound sepsis
• Hematoma in the abdominal wall
• Paralytic ileus, peritonitis/intestinal obstruction.

Delayed Complications
• Chronic PID
• Menstrual irregularities
• Incisional hernia
• Psychological problems
• Post-tubal ligation syndrome: This term is used for abnormal menstrual bleeding, dysmenorrhea following sterilization. This is said to be because of disturbance in ovarian blood supply and thus dysfunction. The existence of which is doubtful.
• Ectopic pregnancy: One-third of pregnancies following sterilization are ectopic
• Regret following sterilization is not uncommon
• Failure: Pregnancy is more common after first year.

Causes
• Luteal phase pregnancy
• Tubal anastomosis
• Clips wrongly placed on round ligaments, mesosalpinx.

Advantages of Permanent Sterilization
• Permanent birth control
• Immediately effective
• Allows sexual spontaneity
• Requires no daily attention
• Not messy
• Cost effective.

Disadvantages of Permanent Sterilization
• Does not protect against STD/AIDS
• Requires surgery
• Risks associated with surgery
• More complicated than male sterilization
• May not be reversible
• Possible regret
• Possibility of post-tubal ligation syndrome.

Reversal
Microsurgery for tubal anastomosis is associated with excellent results, if only small portion of tube is damaged. Success rate is about 70–80%, lowest with electrocoagulation.

Recent Advances
Potential new technologies for female sterilization by tubal occlusion have appeared, namely:
• Transcervical use of chemicals like quinacrine
• Hysteroscopic methods, including silicone implants
• Ablation of the uterine horn endometrium with neodymium-doped yttrium aluminum garnet (Nd:YAG)
• Transcervical placement of metal microspindles through fluoroscopic guidance
• Essure.

WHAT IS ESSURE?
• Hysteroscopic approach to place micro-inserts into the fallopian tubes
• Tissue growth in and around the inserts blocks the fallopian tubes achieving tubal occlusion
• Food and Drug Association (FDA) approved in November 2002.

Steps to Essure Placement
• Paracervical block is administered
• Hysteroscope with attached camera is inserted through the cervix
• Catheter is passed through the hysteroscope and directed to the ostium of the fallopian tube
• Micro-insert is positioned in the proximal portion of the fallopian tube and then detached
• Over the next 3 months, the tissue response and tissue in growth occludes the fallopian tubes
• Hysterosalpingogram (HSG) is done after 3 months to confirm occlusion and location.

Mechanism of Action
Micro-insert is flexible and dynamic and accounts for differences in women. The diameter of the micro-insert is larger trailing into the uterus than within the tubal lumen. This difference in the diameters is intended to prevent migration toward the peritoneal cavity.

Benefits
• No GA required
• No incisions required
• Speed of procedure
• May be performed as an outpatient
• Quick recovery
• Effective.
Considerations

- Patients must use another form of birth control, for at least 3 months after the procedure
- Removal requires surgery
- Reversal is not achievable: In vitro fertilization (IVF) is only option to conceive
- Not all women will achieve successful placement of both micro-inserts
- Physician learning curve.

BIBLIOGRAPHY

INTRODUCTION
Human being is a social animal. Yes, an animal but social. We have been learning this especially from our primary school days. It was also taught that we form and stay in a community which is similar to any other ecosystem that we see in the environment. Evolution is a constant process and one can appreciate that in the society and the social situation.

Health happens to be the prime component of human life and therefore health care services are for the, by the, and of the community. Social work we all have to understand is something that is closely interspersed with this health care. As doctors we have developed a sort of false and egoistical attitude that we are the health care system but it is important that we understand that we are mere a small component of the society, the health care system and what it actually implies.

WHAT IS SOCIAL WORK?
The dictionary meaning goes; “organized work intended to advance the social conditions of a community, especially of the disadvantaged by providing psychological counseling, guidance and assistance especially in the form of social services. Let us consider the various components of this definition; advancement of social conditions, disadvantaged strata, psychological counseling and assistance. Through social work one can promote a social change, solve problem in human relationships, and empower and liberate people to enhance well-being. Utilizing theories of human behavior and social systems, social work intervenes at the points where people interact with their environments. Principles of human rights and social justice are fundamental to social work.

What we are doing through our everyday jobs as a medical professional itself to an extent is social work. But then there also exists a lot of disparity.

Let us go a little in the past. How did hospitals come into being? The elite in the society had family or personal physicians taking care of ailments. The poor and the destitute were through social awareness at that time taken into alms houses to be looked after through the means that society felt appropriate and could shell out. Gradually the elite of the society, the so-called reformers felt the need of having a place for the ill and the ailing to be looked after in better conditions. This thought also was propelled further by some fractions of the society being ready to pay for such services. Thus hospitals mushroomed. But all these primary institutions were essentially charitable institutions and supported by the public sector. In the very recent past when tuberculosis was a dreaded disease without any drugs to treat it we saw the sanatoriums as a major solid socialistic evolution for managing the affected.

An ailing person is not always an easy task to handle. Looking after any ill person mentally or physically is a drain on material as well as emotional resources. It is difficult to handle the ill for various reasons and one can see lot of money being exchanged for such services. The ones who can afford to pay, the ones who cannot are helpless. Added to it increased awareness of health, emergence of newer diseases, early diagnosis of many diseases and availability of many modern treatment modalities have all led the simple caring and nurturing into a huge health care industry (transformation from Vaidyas to Modern Medicine).

Even if it is now a business we cannot forget and are not allowed to ever forget that we are closely entwined with the society in its basics through our profession. Therefore social work is an extremely important part of our existence as
Social work in the medical scenario is an important link connecting the professional to the patient through his environment. This especially becomes relevant in financially and socially challenged situation or in the scenario of government agencies failing in their manifesto of primary care for the needy and poor or the socially deprived. Social work bases its methodology on a systematic body of evidence-based knowledge derived from research and practice evaluation, including local and indigenous knowledge specific to its context. It recognizes the complexity of interactions between human beings and their environment, and the capacity of people both to be affected by and to alter the multiple influences upon them including biopsychosocial factors. The social work profession draws on theories of human development and behavior and social systems to analyze complex situations and to facilitate individual, organizational, social and cultural changes.

As gynecologists we have an altogether a different aspect to deal with. We care for women and the main stay of our practice is closely related to the family. Family or women through whom the society actually is born. Our responsibility actually begins from the birth of a girl child. We as a professional are actually powerful socialists and it is important that each one of us realizes this at the earliest in his practice. Even if we spend few minutes of our consultation with the client in evaluating her social situation, it becomes easy to communicate, to assess, to understand and to treat her disease in a much better way.

One cannot limit our clinical consultation only to the disease process in our clients. Many of our references are based on experiences of our western colleagues and very often we follow these practices blindly. They have set these standards on sound evidence and here again one must attribute this to social work. If one looks at social work as a profession and decides to train for it one will realize that the curriculum is basically and predominantly research-oriented. Everything, the design, the teaching and the practice of social work training is based on research.

Social work addresses the barriers, inequities and injustices that exist in society. It responds to crises and emergencies as well as to everyday personal and social problems. Social work utilizes a variety of skills, techniques and activities consistent with its holistic focus on persons and their environments. Social work interventions range from primarily person-focused psychosocial processes to involvement in social policy, planning and development. These include counseling, clinical social work, group work, social pedagogical work, family treatment and therapy as well as efforts to help people obtain services and resources in the community. Interventions also include agency administration, community organization and engaging in social and political action to impact social policy and economic development. The holistic focus of social work is universal, but the priorities of social work practice will vary from country to country and from time to time, depending on cultural, historical and socioeconomic conditions.

This is the biggest disparity in medical training. The realization dawns very late as a professional and no due returns and lack of time mostly come in the way of research. This is where one could entwine-trained social workers in our establishments. Like we have certain must have professionals as associates from the allied branches like the anesthesiologists, pathologists, pediatricians, etc. we must have a social worker as an important associate. Firstly, we have to realize that we are dealing with that fraction of society which is socially deprived in many ways. Secondly, even a little lateral thinking in every deal with our client we can contribute toward a change for betterment in the society and that itself is social work.

Let us not go on to oncology or psychiatric illnesses where we think the clinical practice rests mainly on social workers. Let us take an example of antenatal patient. From sensitizing her to seek care to plan for her confinement and all this to acquire with relevance to her social situation is where a social worker can help the professional, but such practice we see only in large institutions. The financial constraints are usually the reason given and thought about in small nursing homes as the need has not been completely realized.

What then can we do as far as social work is concerned? We over a period of our training as professionals and practicing in our field acquire a lot of knowledge which could be easily disseminated in the society. Small talks, lectures, camps, informal events all go a long way in doing social work as an individual. That little extra if can be spared, which may not give you much probably in way of material returns immediately, can go a long way in giving back to the society that you live in. What has the society given us would be the next question? Our existence throughout our lifetime is given to us by the society and we owe her that much.

This is on an individual basis. But we are fortunate to be associated to organizations like the Federation of Obstetric and Gynaecological Societies of India (FOGSI) which is strong force to reckon with. Successful and senior professionals through their experiences set examples to follow. Every such new project has gone a long way in creating a social ripple. If all of us join hands we can create a wave. Examples like the Adolescent Health Awareness Programme, the Anemia Chale Jaon Drive, the medicolegal concept go a long way in creating a social change. Our experienced seniors are invited by the policy makers in important health issue like the Prenatal Diagnostic Techniques Act (PNDTA) as an example. THIS TOO IS SOCIAL WORK. IF WE JOIN HANDS TOGETHER we
can then fulfill the important part of the definition “integrated and organizational work”.

The Lord of the universe says: “While constantly struggling for more and more wealth, finally you arrived in your grave. Now you will know the fact” (Holy Quran: 102). It is true that when we realize or know facts about spiritual or economic matters, it is too late. Let us not be too late and start being socially aware and savvy.

**BIBLIOGRAPHY**

1. Demolishing the stigma of "Girl child".
2. Evolution of PNDT ACT: How social work/transformation has evolved? e.g. of BIMARU States—their backwardness and our forward thinking—how far they have to go?
3. Recognition of Women as 1-primary of the Pillars of Society.
4. Women’s education.
Intrauterine Contraceptive Device

INTRODUCTION

An intrauterine contraceptive device is also known as an IUCD. It is a device placed in the uterine cavity and is the world’s most widely used method of reversible birth control. Nearly 15% of women of reproductive age use IUCDs. It is popular because of its effectiveness combined with its long duration. The most widely used IUCDs are copper-bearing IUCDs. Currently nearly 160 million women use this method, over two-thirds of whom are in China where it is the most widely used birth control method, surpassing sterilization. In India, the use of IUCDs by contraceptive users among married women of reproductive age (MWRA) has come down from 13% in 1969 to 4% in 1979, although since the introduction of Copper-T (Cu-T) its use has increased slightly to 5.4% in 1984. According to government publications, IUCDs in the form of Lippes Loop were introduced in the National Family Welfare Program of the Government of India (GOI) in 1965 and have always been considered an important spacing method. Based on the results of clinical trials conducted by the Indian Council of Medical Research, Cu-T 200B was introduced in the program in 1975; subsequently in 2002, Cu-T 380A was introduced replacing Cu-T 200B.

In India, only 1.8% of MWRA use IUCDs. Despite the fact that the government offers IUCD services free of cost, it remains largely underutilized.

Intrauterine contraceptive devices (Fig. 1) are devices made of plastic or metal or a combination of these materials, meant for insertion into the uterine cavity for contraception.

HISTORY AND DEVELOPMENT

From ancient times, different materials have been introduced into the uterus of animals and human beings for prevention of pregnancy. For example, there are quotes that pebbles inserted in the uteri of camels by Arabs and Tweks during long journeys through deserts to protect them from pregnancy. Although it has no basis in history and was meant only for entertainment purposes.

In the 19th century, various stem pessaries, originally meant for treatment of infertility and correction of position of the uterus, were also used to prevent pregnancy. Stem pessaries had small caps, which covered the opening of the cervix, and a stem, which extended up into the lower part of the uterine body and cervical canal. The materials like wood, glass, silver, gold and ivory were used to prepare it. In 1902, Dr Carl Hollweg of Germany introduced wishbone shaped pessaries and tried it in 700 women for prevention of pregnancy. Some of these pessaries were used to procure abortion also. The use of wishbone pessaries was followed by severe infection and brought a bad name upon pessaries.

A German physician, Richard Richter, first introduced the intrauterine device as a contraceptive method for women...
in 1909. The device was ring-shaped and was made of silkworm gut but he never marketed his product and so never got appreciation like Gräfenberg.

The first widely used IUCD was introduced in Germany by Ernst Gräfenberg and became popular in the late 1920s. This was a ring of silkworm gut and silver wire. This device was found to be quite effective. In 1930 at the 7th International Birth Control Conference in Zurich, Switzerland, Gräfenberg presented his illuminating paper. Dr Gräfenberg reported a lower pregnancy rate of 1.6% among 600 women.

In 1934, Japanese physician Tenrei Ota, introduced a device made of gold or gold-plated silver. The device was a ring with a small disc in the center, attached to the ring by three spokes. The Ota ring was used extensively in Japan. The addition of this central disc lowered the IUCDs expulsion rate. These devices still had high rates of infection, and their use and development was further stifled by World War II politics—contraception was forbidden in both Nazi Germany and axis-allied Japan. Both Gräfenberg and Ota rings were criticized so much so that in 1936 the Japanese government condemned the Ota ring, and Gräfenberg was forced to abandon his ring after severe criticism by European doctors for risk of pelvic infection.

The first plastic IUCD, the Marguiles Coil or Marguiles Spiral, was introduced in 1958. This device was somewhat large, causing discomfort to a large proportion of women users, and had a hard plastic tail, causing discomfort to their male partners. The Lippes Loop, a slightly smaller device with a monofilament tail, was introduced in 1962 and gained popularity over the Marguiles device.

The Population Council of the USA conducted a major research and development program for IUCDs and spent about one and a half million dollars between 1959 and 1962. The first international conference on the IUCD was held in New York in 1962, conducted by the Population Council and attended by physicians all over the world who reported their favorable experiences with IUCDs. At this conference Lazav Marguiles of Mount Sinai Hospital, New York and Jack Lippe of Buffalo, New York described their experiences. Both these devices could be inserted through narrow tubes without cervical dilatation into the uterine cavity where on being released they resumed their shapes. Lippe further added barium sulfate to polyethylene so as to render the device radiopaque and fixed nylon threads to the device, which hung through the cervix for easy detection and removal when needed.

At the second world conference in 1974, the Population Council established the cooperative statistical program (CSP) under the direction of Christopher Tietze to undertake evaluation of IUCDs. The CSP studied several types of IUCDs including Lippes Loops A, B, C and D, the Marguiles coil, Birnberg Bow—large and small, Saf-T coil or double coil, steel rings and many others. A life table analysis was carried out of the critical events, pregnancies, expulsions and removals, per 100 women at 1, 2 or 3 years of use. It was concluded that the IUCD was a safe and effective method of contraception and appropriate for use in national family planning programs. From this CSP study, Tietze and Lewit concluded that no single type of IUCD was superior to the others so far as the critical events were concerned. In 1967, Lernes and Davis designed the Dalkon shield, which had a central membrane to increase the area of contact with the endometrium. It soon become very popular in the USA, but was later withdrawn from the market on being found to cause severe infection, which sometimes proved fatal. There are reports of 110 septic spontaneous abortions in women with the Dalkon Shield in place, seven out of them died. Robins stopped international sales of the Dalkon Shield in April 1975.

By the mid-1970s, a second generation of devices also called medicated or bioactive devices, started to be developed and were used to reduce some of the drawbacks such as high expulsion rate, removal rate due to bleeding and pain, and pregnancy rates. In these bioactive devices, plastic IUCDs become carriers for other substances such as metals, hormones and antibleeding agents.

Jaime Zipper from Chile and Howard Tatum developed the first medicated devices in 1969. In these, Copper wires were wrapped around the “T” and “7” devices having a small surface area to reduce bleeding and pain, and to improve efficacy. The addition 200 mm² of exposed copper to the “T” or “7” devices improved the quality. T-shaped devices had lower rates of expulsion due to their greater similarity to the shape of the uterus. Worldwide today, with the exception of the new GynFix, this is the only type of IUCD available.

The multiload Cu-250 and multiload Cu-375 are being tried in different sizes; they have different shapes, and inserters of the withdrawal type.

Since 1973, IUCDs containing hormones are being used. The progestasert contains a reservoir of 38 mg of progesterone in silicone oil and is approved by the USFDA with an effective life of 1 year. Newer devices containing progesterone, effective for 3–10 years, are being tested.

Another group of pharmacological agents being added to IUCDs with a view to reduce bleeding are the fibrinolytic inhibitors tranexamic acid (AMCA) and epsilon aminocaproic acid (EACA).

Various researches are being conducted throughout the world to improve the inserter, the shape and size of IUCDs and by adding different compounds to improve on the present type of IUCDs. An ideal version is still to be invented.

**TYPES OF INTRAUTERINE CONTRACEPTIVE DEVICES**

As we have seen in the history, there are several types of IUCDs developed so far (Figs 2A and B). But only few of them were used consistently. Many of them were discarded in short span because of their serious complications.
There are three types of IUCDs:

**First Generation IUCDs**
Inert IUCDs like Lippe’s loop, Saf-T coil. These are also called as first generation IUCDs.

**Second Generation IUCDs**
Copper containing devices like Cu-T 380A, Cu 7, Multiload Cu-T, Nova T, etc., which are second generation IUCDs.

**Cu-T 380A**
Copper-T 380A intrauterine device (IUD) is a T-shaped device composed of a polyethylene frame measuring 36 mm by 32 mm with 176 mg of electrolytic copper wire wrapped around its vertical stem and two copper sleeves of 68.7 mg of copper, placed on each of the horizontal arms, for a total surface area of 380 ± 23 mm² of copper. The device has a monofilament polyethylene string tied at the base of the stem to create two tail strings that aid in monitoring device’s position and in its removal. The frame contains barium sulfate to permit radiographic visualization. The Cu-T 380A IUCD is Food and Drug Administration (FDA) approved for 10 years of use, although clinical studies indicate high efficacy for at least 12 years and as long as 20 years.

**Efficacy:** The cumulative 5 years pregnancy rate is between 0.3% and 0.6% for the Cu-T 380A IUCD. It is the most effective copper-bearing IUCD in the world. The 10 years cumulative pregnancy rate for the Cu-T 380A is 1.9–2.2%. Because IUCDs act their efficacy is maintained even in women with class 3 obesity.

**Contraindications:** The Cu-T 380A IUCD is not appropriate for women with copper allergies and is not recommended for women with copper storage defects (Wilson’s disease). Labeling states that the Cu-T 380A IUCD should not be used by women at high-risk for sexually transmitted infections (STIs); however, in that situation, concurrent condom use may enable IUCD use. A recent retrospective study of women with a history of sexually transmitted diseases (STDs) or active infections showed that both the IUCDs were safe and effective. HIV-infected women are also appropriate candidates for IUCDs.

Expulsion rates are highest in the first few months after placement and depend on insertion technique and timing of placement within the menstrual cycle. Overall, first-year expulsion rates with the copper T 380A are 5.7% among all users and 2.3% among parous women. After the first year, expulsion rates decline.

**Third Generation IUCDs**
Third generation IUCDs are hormone based devices that work by releasing a progesterone like Mirena, Progestasert.
Most nonhormonal IUCDs have a plastic T-shaped frame that is wound around with pure electrolytic copper wire and/or has copper sleeves. Cu-T 380A is most popular.

Intrauterine contraceptive device today and seen in Figures 3A and B. Cu-T 380A is 32 mm (1.26”) in the horizontal direction (top of the T), and 36 mm (1.42”) in the vertical direction (leg of the T). In some IUCDs, such as the Nova T 380, the pure copper wire has a silver core which has been shown to prevent breaking of the wire. The arms of the frame hold the IUCD in place near the top of the uterus. All copper-containing IUCDs have a number as part of their name. This is the surface area of copper (in square millimeters) the IUCD provides.

In the United Kingdom, the term IUCD only refers to inert or copper-containing devices. There, hormonal uterine contraceptives are considered a different form of contraception than copper IUCDs, and they are distinguished with the term intrauterine system or IUS.

**Fourth Generation IUCDs**
Newer IUCDs or fourth generation frameless IUCDs are not yet in clinical use. The frameless IUCDs are made without
the plastic T-shaped frame common to most other types of IUCDs and consists of several copper cylinders tied together on a string. It is anchored 1 cm deep into the fundus (top) of the uterus. This design is intended to cause less pain and bleeding than framed devices.

**GyneFix**

GyneFix, the newest frameless IUCD, was introduced in Europe in the early 1990s, following 15 years of research to improve ease of insertion and attachment to the uterine wall. It is also available in China and through Marie Stopes International Programs in Latin America, Asia and Africa. Its developer plans to apply for US FDA approval.

Small, noncomparative studies demonstrate promising results for GyneFix in minimizing menstrual blood loss and discontinuation. Randomized controlled trials involving GyneFix have not yet provided clear support for the benefits expected and the expulsion rates have been higher than found in early clinical trials.

The frameless IUCDs require an entirely different insertion technique than the framed IUCDs and the level of skill required to insert them is high. Providers face difficulty with insertion even with the use of a new inserter mechanism, introduced by the developer to simplify insertion. The frameless IUCD is less likely to be expelled when inserted by an experienced provider.

Another frameless IUCD in development, FibroPlant-LNG, releases the progestin levonorgestrel. Based on the design of the GyneFix IUCD, it too is anchored into the fundus of the uterus. FibroPlant-LNG delivers 14 µg of levonorgestrel daily and prevents pregnancy for at least 3 years. Initial studies suggest that FibroPlant-LNG would be highly acceptable and may reduce bleeding.

**INTRAUTERINE SYSTEM**

Hormonal uterine devices do not increase bleeding as inert and copper-containing IUCDs do. Rather, they reduce menstrual bleeding or prevent menstruation altogether, and can be used as a treatment for menorrhagia.

Progestasert was the first hormonal uterine device, developed in 1976 and manufactured until 2001. It was replaced annually, and had a failure rate of 2% per year. As of 2007, the LNG-20 IUS, marketed as Mirena, is the only IUS available. First introduced in 1990, it contains 60 mg of levonorgestrel which elutes 20 mg daily and may be used for 5 years.

A lower-dose T-shaped IUS named Femilis is being developed by Contrel, a Belgian company. Contrel also manufactures the FibroPlant-LNG, a frameless IUS.

Table 1 gives comparison and summary of IUCD and IUS where major difference is of cost.

**MECHANISM OF CONTRACEPTION**

The precise mechanism of action of IUCD is still unknown. It could be a combination of the following:

- Within 24 hours of insertion, there is inflammatory reaction in the endometrium. Phagocytic leukocytes engulf sperms and ova. All unmedicated and copper devices produce an inflammatory or foreign body reaction in the uterus. Numerous polymorphonuclear leukocytes followed by giant cells, mononuclear cells, plasma cell and macrophages appear in the endometrium and uterine fluids, mostly around the devices. Macrophages adhering to the devices are also a source of prostaglandins. In 1969, Wynn and Sawaragi postulated that increased prostaglandin levels produced asynchronous development of the endometrium and increased uterine activity; which may be responsible for the contraceptive effect.

- Copper alters the trace element and enzyme content of the endometrium and is spermicidal. Copper ions are also toxic to sperms.

- There is alteration of uterine and tubal fluids to impair viability of gametes and impede fertilization. The presence of a device in the uterus prompts the release of leukocytes and prostaglandins by the endometrium. These substances are hostile to both sperm and eggs.

- IUCDs containing progesterone maintain high local progesterone levels and in consequence relatively low estrogen levels. They thereby keep the endometrium in the decidual or progestational phase, which hinders implantation. The small amount of progesterone released by these devices does not appear to effect ovarian function. This type of IUCD also alters the cervical mucus, which, in turn, inhibits sperm from passing through the cervix.
Earlier it was suggested that IUCDs act by accelerating ovum transport through hyperperistalsis of the oviducts so that the fertilized ovum cannot be implanted owing to the unpreparedness of the endometrium. This theory could not become substantial.

**EFFECTIVENESS OF CONTRACEPTION**

All second-generation copper-T IUCDs have failure rates of less than 1% per year and cumulative 10-year failure rates of 2–6%. A large WHO trial reported a cumulative 12-year failure rate of 2.2% for the Cu-T 380A with average failure rate of 0.18% per year over 12 years, equivalent to a cumulative 10-year failure rate of 1.8% following tubal ligation.

Mirena is also 99% effective in preventing pregnancy.

The Cu-T 380A device remains effective for up to 10 years; the multiload copper IUCD remains effective for up to 5 years; the levonorgestrel-releasing IUCD is effective for at least 5 years. Most women can use IUCDs safely throughout their reproductive years, if the woman is satisfied with the method and has no problems with it.

**TIMING OF INSERTION**

**Postmenstrual Insertion**

Some doctors prefer to insert the IUCD immediately after menses or during menstruation to verify that the woman is not pregnant at the time of insertion. However, IUCDs may safely be inserted at any time during the menstrual cycle as long as it is reasonably certain that the woman is not pregnant. So the best time is the time convenient for the potential user.

**Postcoital Insertion**

To prevent or interrupt pregnancy following unprotected intercourse IUCDs have been inserted with successful results, even when inserted up to 5 days after coitus.

**Postabortal Insertion**

Studies in various countries including the US, India, Finland, Sweden by the WHO revealed no increased incidence of infection, perforation, expulsion, bleeding or other events.

---

</table>

( Abbreviations: IUCD, intrauterine contraceptive device; IUS, intrauterine system; PID, pelvic inflammatory disease; STI, sexually transmitted disease)
following insertion of IUCD after spontaneous and induced abortion. In an Indian study of 1,000 cases where IUCDs were introduced after menstrual regulation, the expulsion rate and failure rate were found to be much less with the Cu-T200 than with the Lippes Loop. Postabortal insertion has a high acceptance rate. However, there is 5–10 times more chance of expulsion of the IUCD when inserted after second trimester abortion.

**Postpartum Insertion**

Fitting after a delivery is either immediately postpartum, which is not a common practice for obvious reasons or at 4–6 weeks postnatal. But insertion of the IUCD in the postpartum period has a number of advantages, including ease of insertion and convenience to the user; it is particularly of value in developing countries including India, where postnatal care is not satisfactory. Both postpartum and interval insertion after cesarean delivery have been found to be safe and effective. There is no increased risk of perforation, infection or heavier menstrual bleeding following insertion of the IUCD within 10 minutes of delivery of placenta or after delay of 6–8 weeks postpartum as compared to insertion in the interval between menses. The disadvantages of postpartum insertion of the IUCD is its higher expulsion rate and more chances of perforation. Immediate postpartum insertion (within 10 minutes of delivery) seems to be associated with lower rates of expulsion than insertion at other times of puerperium. Various attempts have been made to reduce expulsion rates by experimental IUCDs with added catgut sutures of biodegradable projections, but none has been found to have a lower expulsion rate following postpartum insertion than the conventional Lippes Loop or Cu-T. Careful postpartum insertion technique, placing the IUCD high up in the fundus transversely, is more important than the type of IUCD whether modified or not. Immediate postpartum insertion of the IUCD is best done by means of a sponge-holding forceps or just manually. There is no need of long inserters such as were used earlier.

**Counseling**

Before insertion every woman should be told about the advantage and drawbacks of the procedure and advised to try it and to get it out any time she does not like it. False hopes about hundred percent safety should never be given. Bad counseling is one of the main causes of the lowering of acceptability and continuation rates in countries like India.

**Insertion Technique**

It is advised that medical personnel trained in IUCD insertion should insert IUCDs. The selection of patients, choice of device, timing of insertion and skill of the inserter is critical to the success of the device and can affect how it is accepted and also determine its continuation of use. Rarely during insertion some patients may get syncope and so good resuscitation facilities should be available.

Other research has looked at improving IUCD services by training nonphysicians to provide IUCDs. IUCD insertions by trained nonphysicians are increasing, and some countries, such as the Philippines, have initiated training programs specifically for nonphysicians. Studies in Brazil, Turkey, and the Philippines found that trained health care workers can provide IUCDs as safely and effectively as physicians in many settings. Additional training may be required to ensure correct placement of the IUCD in the uterine fundus to reduce the likelihood of expulsions. Training nonphysicians to provide IUCDs safely and effectively could result in higher use of this method. But at the same time it carries risk in difficult cases as we all know that every case is different.

Most IUCDs are supplied with their inserter in prepacked sterilized plastic containers. The shelf life of the Cu-T 380A IUCD is 7 years. If the date on that IUCD sterilized packaging has expired, the device and its inserter should be discarded.

Perform a bimanual examination to assess the position of the uterus and to rule out pelvic infection. Place the speculum in the vagina. Clean the cervix and vagina with betadine or a similar antiseptic solution. Place a tenaculum on the anterior lip of the cervix. Explore the uterus with a uterine sound. Do not move rod. The Cu-T device and the inserter with the plunger are taken out under sterile conditions just before insertion. The horizontal arm of the device is folded. The tail, the vertical rod and the folded horizontal arm of the device are introduced.
at the top end of the inserter. The adjustable collar is adjusted so the size of the portion of the inserter above it corresponds to the size of the uterine cavity as determined by the introduction of the uterine sound. The solid rod plunger is now introduced into the inserter tube up to the lower end of the vertical arm. The inserter loaded with the device is now negotiated into the uterine cavity till it touches the fundus and the collar touches the external os. The plunger is held firmly with the left arm, and the outer inserter tube is retracted over the plunger with the right hand for about 2 cm, so that the Cu-T device is left high up in the fundus and lies transversely. This is withdrawal technique, which minimizes risk of perforation. The plunger is withdrawn followed by removal of the inserter tube and thread is trimmed so as only 2 cm lies outside external os. In puerperal insertion or in cases with previous uterine surgery, special care is needed.

The woman should be told that the IUCD will not interfere with her sexual act nor will her male partner feel it during intercourse. To detect expulsion she should watch her pads during the next few periods and also watch for falling of T-shaped device during other acts like voiding. Additionally she can feel the tails following menstruation as long as she uses the IUCD (Fig. 5). But at many times it is found that women are not very comfortable for this rather they find it embarrassing.

The woman should report if she cannot feel the tail or if she feels a part of the IUCD inside the vagina or if IUCD is expelled. Though it is common that first few cycles could be slightly heavy she should also report if she experiences persistent irregular bleeding, discharge or if she develops severe pain in the lower abdomen with or without fever. It is necessary to tell about failure of IUCD and rare possibility of pregnancy with IUCD in situ and accordingly she should come for consultation if her period is missed.

The woman should have a routine check-up after the next period and then after 3 months and then every 6 months. Medicated devices should be replaced at intervals depending upon the recommended effective life span of the devices. Table 2 gives the list of situations when she should report health provider for consultation.

**REMOVAL**

The woman can come for removal anytime she desires to have her next pregnancy. If she is not happy with IUCD use or is not convinced with appropriate counseling she can come for removal but it is necessary to offer another suitable method of contraception. If she has continued IUCD use till menopause then it is advisable to remove it 18 months after menopause, if she is less than 50 years or 12 months after menopause, if she is more than 50 years.

**INDICATIONS**

- Its main use is contraception but there are many other indications for which IUCD is used.
- Intrauterine devices can be used as emergency contraception to prevent pregnancy up to 5 days after unprotected sexual intercourse. Insertion of a Cu-T IUCD as emergency contraception is more than 99% effective, making it more effective than emergency contraceptive pills.
- Following adhesiolysis in Asherman’s syndrome, IUCD is inserted to prevent re-adhesions. It is used for 3 months.
- It is also used after hysteroscopic resection of uterine septum, to avoid Asherman’s syndrome.
- Mirena, progestogen IUCD is used in menorrhagia as it reduces menstrual loss.

**ADVANTAGES**

- A single decision leads to effective long-term prevention of pregnancy.
• It is particularly useful for spacing pregnancies and as a real alternative to hormonal contraception in couples in long standing mutually monogamous relationships.
• It is long-lasting. The most widely used IUCD, Cu-T-380A, lasts at least 10 years. Inert IUCDs need never be replaced.
• They are very effective immediately after fitting. No daily action or user motivation is needed. IUCDs are appropriate for women who desire a “forgettable” method of contraception.
• No interference with sex and its use is nonintercourse related. Instead there is increased sexual enjoyment because there is no need to worry about pregnancy.
• Nonhormonal IUCDs are considered safe to use while breastfeeding.
• It can be inserted immediately after childbirth except hormone releasing IUCDs or after induced abortion if there is no evidence of infection.
• It has very low morbidity and mortality.
• Some women especially those using hormonal contraceptives experience 74–90% decrease in menstrual bleeding and reduced menstrual cramping.
• IUCDs are a safe and effective method of reversible, long-term contraception for most women.
• It protects against endometrial cancer.
• It is cost effective.

DISADVANTAGES AND SIDE EFFECTS

Common Side Effects
Menstrual changes which are common in the first 3 months but likely to lessen after 3 months are:
• Longer and heavier menstrual periods
• Increased watery or mucoid discharge
• Bleeding or spotting between periods
• More cramps or pain during periods.

Other Uncommon Side Effects
• Severe cramps and pains beyond the first 3–5 months after insertion.
• Heavy menstrual bleeding or bleeding between periods, possibly contributing to anemia.
• The string may be felt by some men during intercourse. If this is problematic, the provider may cut the strings flushing with the cervix, so they cannot be felt.
• Expulsion of IUCD is noticed in 2–10% cases. This risk is more in nulliparous women or if it is a postpartum insertion.
• Perforation of the wall of the uterus is very rare if the IUCD is properly inserted. The incidence is 1 in 1,000 fittings.
• Does not protect against STDs including HIV/AIDS. Not a good method for women with recent STDs or with multiple sex partners.
• Pelvic infection—not increased when risk of STDs is low. But on high-risk, pelvic inflammatory disease (PID) is more likely to follow STD infection if a woman uses an IUCD. It is advisable to rule out infection before insertion as this PID can lead to infertility.
• Risk of ectopic pregnancy is less than in patients using no contraception for obvious reason that there are fewer fertilizations in patients using IUCDs. However, patients who use copper IUCDs are less protected against ectopic pregnancy than oral contraceptive users or those using other methods.
• With hormonal IUCDs, women may experience changes in bleeding pattern, headache, breast tenderness, acne, weight changes or mood changes. But these changes usually decrease over time.
• It is possible to minimize these side effects by avoiding use of IUCDs in following situations.

CONTRAINDICATIONS

Absolute
• Active pelvic infection or history of infection within last 3 months
• Suspected pregnancy
• Suspected genital malignancy
• Previous classical cesarean section.

Relative
• Uterine fibroids, specially grossly distorted cavity
• Congenital anomalies of the uterus, when cavity is less than 5 cm
• Previous ectopic pregnancy
• Menorrhagia, unless it is mild
• Metrorrhagia
• Severe dysmenorrhea
• Severe cervical stenosis
• Moderate to gross anemia
• Copper allergy including Wilson’s disease
• Valvular heart disease especially previous history of endocarditis
• Insulin dependent diabetes
• Immunosuppressive therapy.
  If there is a history of ectopic pregnancy or if there is heart disease or in nulliparas, it is better to avoid IUCDs. In 1985, the American College of Obstetricians and Gynecologists had advised not to use IUCDs in women who have not had children or who have multiple partners, because of the risk of PID and possible infertility. But in other cases it can be used even in nulliparous women.

The WHO medical eligibility criteria for contraceptive use and RCOG Faculty of Family Planning and Reproductive Health Care (FFPRHC) UK, medical eligibility criteria for contraceptive use lists the following as conditions where
insertion of a copper IUCD is not usually recommended or conditions where a copper IUCD should not be inserted.\textsuperscript{30,41}

**Conditions where the Theoretical or Proven Risks usually Outweigh the Advantages of Inserting a Copper IUCD**

- **Postpartum:** Between 48 hours and 4 weeks (increased IUCD expulsion rate with delayed postpartum insertion)
- Benign gestational trophoblastic disease
- Ovarian cancer
- Very high individual likelihood of exposure to gonorrhea or chlamydial STIs
- AIDS (unless clinically well on antiretroviral therapy).

**Conditions which Represent an Unacceptable Health Risk if a Copper IUCD is Inserted**

- Pregnancy
- Postpartum puerperal sepsis
- Immediately following postseptic abortion
- Before evaluation of unexplained vaginal bleeding suspected of being a serious condition
- Malignant gestational trophoblastic disease
- Cervical cancer (awaiting treatment)
- Endometrial cancer
- Distortions of the uterine cavity by uterine fibroids or anatomical abnormalities
- Current PID
- Current purulent cervicitis, chlamydial infection, or gonorrheal STIs
- Known pelvic tuberculosis.

While nulliparous women are somewhat more likely to have side effects, this is not a contraindication for IUCD use.

**COMPLICATIONS**

**Infection**

Some barrier contraceptives protect against STDs. IUCDs do not protect against STDs or PID.

On the contrary, insertion of the IUCD may introduce bacteria into the uterus. The insertion process carries a small, transient increased risk of PID in the first 20 days following insertion.\textsuperscript{42} It is very important that the provider use proper infection-prevention techniques during insertion.

Recent studies also have investigated the possibility that the increased menstrual bleeding and upper genital tract infections associated with IUCDs may increase the risk of HIV among IUCD users. Data from several studies, however, have not demonstrated an increased risk.\textsuperscript{43}

**Heavy Menstrual Periods**

After IUCD insertion, menstrual periods are often heavier, more painful, or both—especially for the first few months after it is inserted. On average, menstrual blood loss increases by 20–50% after insertion of a Cu-T IUCD; increased menstrual discomfort is the most common medical reason for IUCD removal.\textsuperscript{44} But in fact in many cases, bleeding gets controlled in 2–3 cycles.

**Uterine Perforation**

It is generally caused by an inexperienced provider and is very rare. It usually occurs during insertion itself due to faulty technique. It is a myth that IUCD travels in abdominal cavity.

If the patient complains of sudden significant pain during the insertion procedure or uterine sounding or if the loaded IUCD inserter tube passes into the uterus beyond 9–10 cm without fundal resistance being felt, stop the procedure and remove the IUCD if it has been inserted. Observe the patient for signs of intra-abdominal bleeding (e.g. falling BP, rising pulse, severe abdominal pain, tenderness, guarding, and rigidity). Take the patient’s blood pressure and pulse every 15 minutes for 90 minutes. If there are signs of intra-abdominal bleeding, it is managed accordingly. Otherwise schedule a return checkup after 1 week and help the patient choose another contraceptive method in the meanwhile. Reinsertion can be attempted after the next menstrual cycle.

It is to be remembered that if the IUCD device has been inserted into the abdomen, then the IUCD needs to be removed, preferably by laparoscopy. Copper-containing IUCDs induce an inflammatory reaction causing adhesions and therefore should be removed promptly. Progesterone-containing devices do not induce similar intraperitoneal adhesions; however, most providers also prefer prompt removal.

**Expulsion**

This is more common in younger women, women who have not had children, and when an IUCD is inserted immediately after childbirth or abortion. Women should check the string of the IUCD at least once per menstrual cycle to verify that it is still in place.

**Missing or “Lost” Threads**

It indicates:

- Pregnancy
- Expulsion
- Threads drawn up into the uterus.

Assessment of the patient with examination, ultrasound scan, or X-ray if necessary, will be required. It is managed in this way:

- Always consider the woman with lost threads to be either already pregnant, or at risk of being so
- Determine whether patient is pregnant
- Explore cervix with narrow artery forceps, under direct vision. Gently open and close jaws and withdraw. The majority of threads will be found with this procedure.
- If unsuccessful consider ultrasound to establish position or proceed to exploration of uterine cavity with retriever
hook. Needs appropriate analgesia, e.g. mefenamic acid 500 mg.
- If still unsuccessful, refer for ultrasound, hysteroscopy or laparoscopy if extrauterine.
- If patient elects for termination of pregnancy, the IUCD can be removed at time of surgery.
- If patient is pregnant with IUCD in situ and wishing to proceed to full-term, gentle removal in the first trimester has been found to halve the miscarriage rate.\textsuperscript{45}

**Ectopic Pregnancy**

The risk of ectopic pregnancy to a woman using an IUCD is lower than the risk of ectopic pregnancy to a woman using no form of birth control. However, if pregnancies that do occur during IUCD use, a higher than expected percentage (3–4%) are ectopic.

However, there are many reports saying that, IUCD use is not associated with an increased risk of PID, or ectopic pregnancy, or of subsequent infertility.

**Failure**

If pregnancy does occur, presence of the IUCD increases the risk of miscarriage, particularly during the second trimester. It also increases the risk of premature delivery. These increased risks are reduced if the IUCD is removed after pregnancy is discovered. IUCDs are also not associated with birth defects or other pregnancy complications. Before 12 weeks there is a 50/50 chance of miscarriage whether the device is removed or not, but early removal prevents possible midtrimester miscarriage. Removal very early carries a lower than 50% association with miscarriage.

**Allergic Reactions**

A few case reports have attributed eczematous dermatitis and urticaria in users of copper-releasing IUCDs to systemic copper allergic contact dermatitis, but some dermatologists are skeptical of this because the amount of copper released daily by an IUCD is only a small percentage of the required amount of copper (an essential trace mineral) absorbed daily from the diet, and because copper is an extremely rare cause of allergic contact dermatitis with a low sensitizing potential.\textsuperscript{46}

**Risk of Cervical or Endometrial Cancer**

Although it was hypothesized that irritation of the cervix and endometrium by an IUCD might cause cancer, no association has been found. On the contrary, The Cancer and Steroid Hormone Study of the Centers for Disease Control and Prevention found a protective effect against endometrial cancer (OR = 0.50; 95% CI, 0.3–0.8) with IUCD use.\textsuperscript{47} This protective effect increased with duration of use but did not reach statistical significance. Several other studies have also demonstrated a protective effect of the IUCD against endometrial cancer. It is hypothesized that the IUCD introduces structural changes in the endometrium, thereby altering its sensitivity to circulating hormones.

**SUMMARY**

Table 3 depicts summary of commonly used IUCD, Cu-T 380A.

The IUCD is a safe, cheap, effective and convenient method of contraception, needing no repetition and not interfering with sexual activity. In spite of this its acceptability

*(Abbreviations: BC, birth control; STD, sexually transmitted disease)*
is not up to the mark, mainly because of drawbacks such as bleeding, pain, expulsion and infection. Its continued use depends a lot upon the attitude and social customs of the patient towards slight irregular bleeding, which happens commonly in the first few months, and also upon the attitude of the operator and the availability of other methods of contraception.

Emergency Contraception

DEFINITION
Postcoital contraception or emergency contraception (EC) as it is called now, is a method of using contraceptives to prevent pregnancy following unprotected or unintended intercourse.

Various methods that can be used are either hormonal [estrogens, oral contraceptive pills (OCPs), progestin-only pills (POPs), danazol], nonhormonal (RU-486, Ormeloxifene) or mechanical (IUD). The exact mechanism of action of these agents is dependent on the event of ovulation and its relation to the timing of intercourse and the use of any of the methods.

Added to the World Health Organization (WHO) list of essential drugs in 1996, EC is now recognized as an essential component of contraceptive choice. If EC is used when a couple is at risk of an unintended pregnancy, half of the estimated 3.5 million unintended pregnancies could have been prevented.

INDICATIONS
Situations in which EC is indicated are:
- No contraceptive was used when intercourse took place
- A male condom slipped, broke or leaked
- Diaphragm or cervical cap was incorrectly inserted, dislodged during intercourse, was removed too early, or was found to be torn
- Missing one or more combined oral contraceptive pills (COPs) at the beginning or the end of the pack so that the pill free interval is prolonged beyond 7 days
- Missing one or more POPs
- Improper insertion or removal of a female condom
- Placement of penis in-between female condom and vaginal wall
- Error in practicing coitus interruptus or periodic abstinence
- Partial or total expulsion of intrauterine device (IUD)
- Exposure to possible teratogen such as a live vaccine or cytotoxic drug
- In cases of rape or incest.

Out of these, contraceptive accidents form the major component.

An ongoing pregnancy is the only contraindication to most methods of EC.

A consensus statement sponsored by Family Health International, The Population Council, International Planned Parenthood Foundation and the World Health Organization was published in 1995. This group of 24 experts identified the following three hurdles that have to be overcome, in order to make EC available to all women.

1. Inform patients and doctors about EC so that women know about it before they need it.
2. Manufacturers of EC to provide more publicity and information.
3. All health care providers to change their concept on mode of action. Emergency contraception prevents pregnancy rather than acting as an abortifacient.

EPIDEMIOSOCIAL ASPECTS
On the basis of the six nationally representative studies, the United Kingdom has the highest rates (12%) of women ever using emergency contraception. By contrast, 4% of women in Finland reported the same, and only 1% of women in the United States of America and Nigeria said they have used the method.

Studies also reveal that emergency contraception is indeed popular with young people when they know about it. A study of a teen clinic in Nottingham, UK found that 17% of the clinic visits were for emergency contraception. Perez, who conducted a study of youth center clinics in three cities in Spain, found that 25% of the visits were for emergency contraception.
CHAPTER 58

Emergency Contraception

MODE OF ACTION

Estrogen, combination OCPs, POPs and danazol act in different ways to prevent a pregnancy, depending on when the method is administered. If administered before ovulation, disruption of follicular growth, development and maturation is noted. This disruption can lead to anovulation or delayed ovulation with a change in hormone production during the luteal phase of the menstrual cycle. Postovulatory treatment probably has an effect on the endometrium. However, these methods cannot hamper an ongoing pregnancy.

Estrogens

In 1920s, the estrogen components of ovarian extracts were used for their ability to prevent pregnancies. Since then various schedules were tried. But, the side effects in estrogen users were more severe, hence are not in use at present.

Oral Contraceptives

Combination Pills

In 1977, Yuzpe and Lance published their first article that showed that 500 µg (0.5 mg) of ethinyl estradiol (EE) and 2 mg of levonorgestrel (LNG) in two divided doses over the course of 12 hours within 72 hours of unprotected intercourse could be used as a method of EC. The primary advantage of this regimen, which came to be known as the “Yuzpe Method” (Table 1) is a 125-fold reduction in the EE content and a decrease in overall length of drug administration.

In this landmark study, 608 women were treated, of which 464 admitted to regular menstrual cycles and only 152 had unprotected intercourse at the midcycle. Only one pregnancy was documented in a woman who was exposed at midcycle and started the medication 70 hours after intercourse. The pregnancy was terminated by vacuum aspiration and pathologic evaluation of placenta revealed fibrinoid necrosis of majority of the chorionic villi. Sixty-six percent of patients experienced nausea and 19% emesis.

The various mechanisms by which this regimen seems to act are:

- Suppression or delay of ovulation
- Disruption of luteal function or luteolysis
- Desynchronization of endometrium through the effect on endometrial enzymes and the effect of endometrial progesterone receptors with interference of downregulation
- Accelerated ovum or zygote transport through the tube.

Five years later, Yuzpe et al. published as a follow-up study that documented 11 pregnancies in 692 women who adhered to previous protocol. Of this group, 451 patients were noted to have regular cycles. Of these women with regular cycles, 101 were exposed before midcycle, 217 at midcycle and 133 after the midcycle. Of the 11 pregnancies, 9 were in women with regular cycles and 2 were in those with irregular cycles. In those exposed after the midcycle, one pregnancy occurred in a woman who vomited after she took the pills. Nausea and/or emesis occurred in 51.7% of all patients. Other side effects were minimal.

Trusell et al., analyzed the results of nine published studies in which the effectiveness of this regimen was assessed when treatment was initiated one, two and three days after midcycle unprotected intercourse. The analysis showed that the first tablet needs to be taken immediately after intercourse, allowing the women to go to a health care facility to receive medication the day following unprotected intercourse without a decrease in effectiveness.

In a large Canadian study, 30% of the subjects treated with this regimen reported having nausea without vomiting and another 20% experienced both nausea and vomiting. These investigators included an antiemetic (50 mg tab of dimenhydrinate) in the package and instructed the women to take it along with the second dose of OCPs, if they experienced nausea after the first dose. The time of onset of subsequent menses was also slightly decreased in the users of this regimen.

This regimen is associated with lower rates of side effects such as abnormal bleeding, delayed menses and gastrointestinal (GI) disturbances. In addition, due to a one day treatment regimen, patient compliance is much improved. As a result, this method is more widely used than high dose estrogens for EC. Grossman et al. have reported an underutilization of this method in the US due to lack of public awareness. The WHO criteria (medical eligibility criteria) for emergency contraceptive pills is presented in Table 2.

Progestin-only Pills

Pills containing levonorgestrel have been shown to be equally effective as the Yuzpe method for EC. Ho and Kwan, randomized 424 women to use the Yuzpe method and 410 to the levonorgestrel group. Comparative study between Yuzpe regimen and progestin-only pills (POPs) as EC is shown in Table 3.
Levonorgestrel is administered as 0.75 mg tablet within 72 hours of intercourse and is to be repeated after 12 hours. Though 18.2% of the combination pill users and 19.3% of the progestin-only pill users continued to have intercourse during the cycle, only 3.5% of the Yuzpe group and 2.9% of the POP group became pregnant.

In 1998 WHO published a well-designed randomized controlled trial showing higher efficacy for the progestogen-only method compared with the Yuzpe method. Failure rates were 3.2% and 1.1% respectively.

Hence, when compared with the Yuzpe method, the progestogen-only regimen is equally effective with lesser incidence of side effects such as nausea, emesis and breast tenderness which are caused due to estrogen, and are hence not encountered.

Vomiting following LNG administration is unusual, occurring in only 1% of women. Nausea is reported more frequently (14%). If a woman vomits within 2 hours of taking levonorgestrel emergency contraception (LNG EC), she should take a further dose as soon as possible. Antiemetics are not routinely recommended. An IUD should be considered for a woman experiencing persistent vomiting with oral EC.

Cycle disturbances are common after LNG EC. In the WHO trial, 16% of women experienced bleeding (unrelated to expected menstruation) in the 7 days following treatment. Around 50% of women menstruated a few days earlier or a few days later than their expected practice as women and clinicians generally rely on the reassurance of menstruation as confirmation that EC has been effective and pregnancy has not ensured. It may be difficult to differentiate between nonmenstrual bleeding in the early days after EC and actual menstrual bleeding. Clinicians and women should always err on the side of caution, and undertake pregnancy testing if there is any doubt that menstruation has followed EC use.

Ectopic pregnancies have been identified following administration of LNG EC in case series, however the overall risk does not appear to be increased following LNG EC. There is insufficient postmarketing data to allow accurate assessment of risk. Clinicians and women should be alert to the possibility of an ectopic pregnancy, but the risk is likely to be small.

At the present moment, the United States Food and Drug Administration (USFDA) has approved both combined OCPs and POPs for EC use. These drugs have been marketed as a four tablet pack along with a pregnancy test device in most countries. At the Consortium of Emergency Contraception which was held in New Delhi, India, in January 2001, this regimen was selected as a “dedicated product”.

A WHO multicentric trial was conducted in order to simplify the LNG regimen. A single dose of 1.5 mg of LNG was as effective as doses given 12 hours apart up to 120 hours after exposure.

### Intrauterine Device

The use of IUD as postcoital contraceptives is also referred to as mechanical postcoital contraception. It was first used in 1976 by Lippe et al. as a postcoital contraceptive. Intrauterine device can be used as an effective method of EC up to 7 days after exposure.

The exact mechanism is not precisely known, but the various postulated mechanisms are as follows:

- **Intrauterine device may have an effect on tubal ciliary motility to disrupt the transport of the oocyte or the embryo.** The IUD itself or its copper ions may also hamper the ability of an embryo to implant. It acts before implantation because there was no evidence of a rise in beta human chorionic gonadotropin (β hCG) level following IUD insertion as EC. Copper is also known to be both spermicidal and blastocidal. All these factors contribute to its effectiveness up to 7 days after intercourse has occurred.

- **Intrauterine devices (IUIDs) with banded copper on the arms and containing at least 380 mm² of copper have the lowest failure rates and should be the first-line choice, particularly if the woman intends to continue contraception.**

- **Fasoli et al. summarized the results of four published studies from nine countries involving 875 women who utilized this technique.** Only one pregnancy resulted in these women following copper-IUCD insertion.
The failure rate was consistently less than 0.1% in most studies. Hence, IUDs have the lowest failure rate of any method of EC.

- The primary side effects associated with this method are uterine cramping and vaginal bleeding or spotting.
- One of the biggest advantages of IUDs is that it can be used as an ongoing method of contraception. However, it should not be used in patients in whom the device would be contraindicated like women who have pelvic inflammatory disease (acute, recent or recurrent), distorted uterine cavity, or multiple sexual partners.
- Though IUDs have been shown to be effective, they are infrequently used. When physicians were polled regarding the utility of IUDs for EC, they stated that they thought the obstacles of using the IUD were the possible risk of pelvic inflammatory disease or the amount of time it took to place the device (Fig. 1). This study demonstrated that physicians should become more comfortable with IUD use and should consider IUD for use as an EC. So far, no manufacturer of IUDs has yet applied for USFDA approval to market IUDs as an EC product. Hence, it is infrequently prescribed by clinicians and very few women are aware of its utility, effectiveness, accessibility and safety as an EC.

**Danazol**

Danazol is an androgen analogue that primarily has been used in daily dosage ranging from 400 mg to 800 mg for patients for endometriosis, inducing a pseudomenopausal state.

Studies concerning the effectiveness of danazol as an EC have not been encouraging. Incidence of nausea and emesis were lower than that seen with Yuzpe method. Nevertheless, the effectiveness of danazol as an EC was unacceptable.

In those women, who desire a continuing need for contraception after the cycle in which these drugs (i.e. danazol and LNG) are used, one of the conventional methods needs to be prescribed. Ormeloxifene has also been used as an EC in a dose of 60 mg (2 tab) within 72 hours and 2 tablets within the next 12 hours.

**Antiprogestins (RU-486: Mifepristone)**

Antiprogestins are a family of compounds that block the progesterone receptor. Progesterone is important in endometrial development, ovulation and pregnancy continuation. Any disruption to the progesterone receptor could produce an adverse effect on follicular development, implantation and maintenance of pregnancy.

The most commonly studied antiprogestin as an EC is RU-486 (mifepristone). When RU-486 is administered as a single dose of 600 mg, within 72 hours of unprotected intercourse, it is as efficacious as the Yuzpe method or Danazol.

In the three studies that examined all three methods the failure rates were RU-486 (0–0.4%), Yuzpe method (1.3–2.6%) and Danazol (3.5–4.7%). Also, compared with Yuzpe method, RU-486 users had low rates of nausea (70% vs. 37%) and emesis (22% vs. 3%). Women using Yuzpe method had a higher rate of irregular bleeding, while those using RU-486 had delayed menses. Because of this delay, further intercourse should be avoided. The patient is to be reassured that a postponed cycle may not be a result of pregnancy. If menses do not occur by 3 weeks, a pregnancy test is mandatory.

Greater utility of RU-486 as an EC, will help improve patient compliance, decrease adverse effects and as a result medical or surgical abortions and the social implications brought on by the delivery of an unwanted pregnancy.

A dose of only 10 mg has been shown to be a highly effective method up to 5 days after unprotected coitus.

### CONTRAINDICATIONS

The WHO Medical Eligibility Criteria for Contraceptive Use advises that there are no medical contraindications to the use of hormonal EC. The Summary of Product Characteristics (SPC) advises caution in women with hepatic dysfunction, hereditary problems of galactose intolerance, the Lapp lactose deficiency or glucose-galactose malabsorption. Women with severe malabsorption syndromes (such as Crohn’s disease) may experience a reduction in efficacy of oral EC. Additionally, any women known to have hypersensitivity to LNG or any of the other components of the tablet should use oral EC with caution.

Use of an IUD for EC carries the same contraindications as does routine IUD insertion. For most women, benefits of IUD use outweigh risks (WHO Category 1, “unrestricted use”) or (WHO Category 2, “benefits generally outweigh risks”). Risk of sexually transmitted infections (STIs), previous ectopic pregnancy, young age, and nulliparity are not contraindications to IUD use.
DRUG INTERACTIONS RELEVANT TO EMERGENCY CONTRACEPTIVE USE

- Women using liver enzyme-inducing drugs should be advised that an IUD is the preferred option for EC.
- Women who are using liver enzyme-inducing drugs who are given 0.75 mg tablets of LNG should be advised to take a total of 2.25 mg (three tablets) as a single dose, as soon as possible and within 72 hours of unprotected sexual intercourse. This use is outside the product license.
- Women who are using liver enzyme-inducing drugs who are given 1.5 mg tablets of LNG (Levonelle 1500) should be advised to take a total of 3 mg (two tablets) as a single dose, as soon as possible and within the 72 hours of unprotected sexual intercourse. This use is outside the product license.
- Women using nonliver enzyme-inducing antibiotic (short- or long-term) should follow the normal LNG regimen (1.5 mg within 72 hours of unprotected sexual intercourse).
- There are no drugs that are known to affect emergency IUD use.

PRACTICAL MANAGEMENT FOLLOWING A REQUEST FOR EMERGENCY CONTRACEPTION

1. Detailed history about:
   - Last menstrual period (LMP)
   - Past menstrual cycles
   - Timing of unprotected acts/acts of coitus
   - Failure of contraceptive method
   - Sexual history
2. Assess the necessity for EC
3. Explain proper use
4. Discuss effectiveness and failure rates
5. Discuss side effects
6. Counsel regarding need for ongoing contraception.

AFTER CARE AND FOLLOW-UP

Usually, follow-up is recommended within 3 to 4 weeks of treatment. However, the patient should report immediately if she has heavy bleeding or lower abdominal pain. She should also seek immediate help if her next period is exceptionally scanty or is delayed. In such a scenario, pregnancy should be ruled out and if not pregnant, confirm that the woman is correctly using an effective contraceptive method.

Following LNG EC, more than 80% of women menstruate before, or within 2 days after, their expected date; and 95% menstruate within 7 days after their expected date. Women should be advised to have a pregnancy test if menstruation is delayed by more than 7 days, or is lighter than usual. Clinicians should always consider the possibility of ectopic pregnancy in such women.

An emergency IUD can be removed after the next menstruation without risk of pregnancy, provided no unprotected sexual intercourse has occurred since menses or if hormonal contraception was started within the first 5 days of the cycle. In the case of a woman who has not menstruated following emergency IUD insertion, the device can be removed after 3 weeks as long as it is reasonably certain that she is not pregnant.

In the case she is pregnant, counseling regarding pregnancy should be done. If the woman desires termination of pregnancy (which most women will desire), she should be counseled about the various techniques of medical termination of pregnancy (MTP).

Long-term contraception should be discussed. Combined oral contraceptive pills can be started on the 1st day of the next period. Barrier methods and IUCDs can be used immediately. Injectables can be initiated within a week of the next period. Advance provision of LNG can be offered to women to increase early use when required.

ROLE OF VARIOUS ORGANIZATIONS IN EMERGENCY CONTRACEPTION (FLOW CHART 1)

The WHO expert committee on the use of essential drugs added EC in its list in December, 1995. In June 1996, an advisory committee of the US FDA declared the Yuzpe regimen safe and effective and urged its wider availability.

A national consensus on EC was organized under the auspices of WHO and AIIMS, New Delhi, India, in January 2001 to develop a strategic approach and to plan guidelines for EC.

The Indian Council of Medical Research (ICMR) and the Department of Family Welfare, Government of India have decided to undertake projects in order to obtain information for the purpose of introducing EC in the National Family Planning Program.

In 2003, the Federation of Obstetric and Gynaecological Societies of India (FOGSI) in association with Reliance Mobile initiated an Emergency Help Line for EC. This helpline was available in more than 600 towns and cities all over India with the cost of that of a local phone call only.

However, the promotion of EC in India needs careful planning and infrastructure for an effective implementation. Government agencies, medical bodies, NGOs and women groups need to have cooperative and synergistic role in order to enhance the accessibility of EC.

CONCLUSION

Postcoital contraception has a definite place in the prevention of unwanted pregnancies in modern society. Hormonal methods are all very effective, but IUDs are the “gold standard”.

The use of EC as a repetitive method of contraception should be strongly discouraged. At the time of EC administration, plans should be made to use an ongoing contraceptive pill or device and further acts of unprotected coitus should be discouraged.

In developing countries, the use of this method will have tremendous impact, if the drugs are supplied to the patient via medical or paramedical staff. Through such measures, people can be better motivated or induced to use usual contraceptive measures; thus EC can be used as a recruitment service. Future liberalization in the distribution of emergency contraceptive as over-the-counter drugs (OTCs) will lead to a larger utility of EC. Increased female literacy and health educational programs, will lead to greater community based awareness.

**BIBLIOGRAPHY**

Women are not dying because of diseases we cannot treat. They are dying because societies have yet to make the decision that their lives are worth saving.

—Mahmoud Fathalla MD PhD, 1997

PROBLEM OF UNSAFE ABORTION

Unwanted/unplanned pregnancies are a fact of life. Human beings in the reproductive age group are more often than not exceptionally fertile. Even if contraceptive coverage were to be encompassing all, there would still be unplanned pregnancies due to method or human failure attributable to the contraceptive methods.

It therefore stands to reason and is also borne out by statistics that women need safe services for induced abortion. Approximately 6.7 million induced abortions take place in India annually. When abortion is safe, it is an exceptionally simple procedure with an exceedingly low mortality. However, unsafe abortions are a major killer of women.

Unsafe abortion by itself accounts for at least 13% of maternal mortality worldwide and as much as 20% in parts of Africa and Asia, making it one of the leading causes of maternal death.

About 4 million (40 lakhs) illegal/unsafe abortions take place in India. It is estimated by the World Health Organization (WHO 1994) that in the Indian subcontinent 15–24 unsafe abortions takes place per 1,000 women aged 15–49 years. It is estimated (WHO, 1994) that in India 70–89 women per 100,000 live births die from unsafe abortion, the risk of death is 1 in 250 procedures.

BACKGROUND

It is a completely unfounded belief that restricting abortions legally can bring down the number of abortions. Some of the world’s highest abortion rates are in countries where the procedure is most restricted, such as Chile, Peru, Nigeria and the Philippines. Some of the lowest rates are in countries like the Netherlands, Sweden and France, where abortion is an accepted part of comprehensive women’s healthcare.

Up until the medical termination of pregnancy (MTP) act was passed, providing abortion remained punishable under the Indian Penal Code (IPC, 1860) Section 312 which stated that “Any one voluntarily causing miscarriage to a woman with child, other than in good faith for the purpose of saving her life is punishable by imprisonment (simple or rigorous) and/or a fine”.

Sections 313-316 of the IPC dealt with the punishment to be meted out when there was a death due to procedure as up to 10 years imprisonment and fine, extending up to life imprisonment where the abortion was conducted without consent.

The Shantilal Shah Committee was set up to stem the high maternal morbidity and mortality associated with illegal abortions and it recommended a broadening and rationalization of laws related to abortion in 1966. The MTP Bill was introduced to the Rajya Sabha in 1969, referred to Joint Select Committee Review and finally passed as the MTP Act in 1971. The Act was enforced nationwide from April 1, 1972 and adopted by Kashmir and Mizoram in 1980. At present all States and Union Territories except Sikkim are implementing the Act.
THE MEDICAL TERMINATION OF PREGNANCY ACT

Although a relatively brief piece of legislature the MTP act is rich with meaning and implications for all healthcare providers. It is not possible for this article to cover the act in every detail and nuance but I hope that the gist of the act can be distilled and presented to you in the following paragraphs:

The stated aim of the act was “An Act to provide for the termination of certain pregnancies by registered medical practitioners and for matters connected there with and incidental thereto.”

There are a few important facts to be kept in mind whilst analyzing the MTP act.

The first is that it does not as yet confer upon women the right to have an abortion legally. It is a wrong impression that abortion is available on demand in our country. What the act does, is lays down certain indications, albeit liberal, which may make abortion services available to most women. As a counterpoint to this is the second fact that the act makes the service of providing safe abortion almost completely provider centric where the onus on decision making for the abortion is legally with the provider. Thus the thrust of the act needs to be changed to make it easier for those seeking the service and make it woman centric.

The other fact is that up until now the act was a protective act for qualified service providers. This protection was extended provisional to the provider meeting all the demands of the act. The punishments for not following the act were as would be laid down in the IPC. The amendments however, have changed this and punishment is now incorporated into the act itself. There is provision for rigorous imprisonment for a minimum of 2 years which may be extended up to 7 years under the amendments to the act.

When Pregnancies may be Terminated?

According to Section 3 (2) based on opinion formed in good faith, “pregnancies not exceeding 12 weeks can be terminated with single opinion. Pregnancies between 12 weeks and 20 weeks require opinion of not less than two medical practitioners.”

This section indicates that any induced abortion after 20 weeks is illegal, except to save maternal life as per Section 5. Thus whatever else may be the indication a pregnancy beyond 20 weeks may not be terminated except to save maternal life.

Grounds for terminations as per Section 3 (2) allowed for the following indications:

- Risk to life or risk of grave injury to physical or mental health
- Substantial risk of physical or mental abnormalities if the child were born

This section indicates that the responsibility to judge the necessity and indication lies with the physician who has to opine in good faith regarding valid legal indication for the termination of pregnancy.

Explanation 2 of the section specifies that “Where any pregnancy occurs as a result of failure of any device or method used by any married woman or her husband for the purpose of limiting the number of children, the anguish caused by such unwanted pregnancy may be resumed to constitute a grave injury to the mental health of the pregnant woman”. The explanation does not elaborate on the method of contraception. It is quoted as being the most common indication on records for an MTP.

The Issue of Consent

Consent has always been a controversial issue to the practicing gynecologist particularly when it relates to matters of reproductive health. However, the act is unequivocal about the type of consent required and the format (Form C) for the same.

Valid legal consent as per Section 2 (4) is mandatory. In the case of majors (women above the age of 18) termination of pregnancy can proceed with their valid consent. It is important to note here that the law does not require spousal or anybody else’s consent for women who are majors. Thus the practice of taking consent from either the spouse or any other family member is legally not valid.

In the case of clients below the age of 18 or mentally ill persons termination can only proceed with the consent of guardian. However, the definition of guardian is tenuous at best.

By Whom Pregnancies may be Terminated?

The act is quite clear as to the qualifications required for a provider to perform MTP’s.

Qualifications of a practitioner registered in the State Medical Register are defined in Section 2 (d) of Rules as a doctor trained in the allopathic system of Medicine (any recognized medical qualification as defined in clause (h) of section 2 of the Indian Medical Council Act, 1956 (102 of 1956, whose name has been entered in a State Medical Register) who further has:

- PG degree or diploma in Gynecology and Obstetrics
- Registered before commencement of Act with 3 years experience in the practice of gynecology and obstetrics
- Registered after commencement of the Act if:
  - House surgeon (6 months) in gynecology and obstetrics
  - Experience of over 1 year in gynecology and obstetrics
  - Assisted or performed 25 MTPs in a training Institute (observed 10, assisted 10 and performed 5 procedures under supervision)
This has been one of the contentious sections as it disregards the talents and potential of the doctors trained in the alternative systems of medicine who have undergone structured training. Consideration should be given to this thought and training systems devised to bring them into the ambit of structured healthcare programs. Needless to say this may be made possible only after rigorous training.

Where Pregnancies may be Terminated?

There is no ambiguity in the act that an MTP performed in a center which is not registered is an illegal abortion. The provider who performs the MTP in an unregistered center steps out of the protection that the MTP act offers and is liable to punishment. It is therefore essential that both the place where the procedure is performed and the provider fulfil the requirements of the Act.

Registration of place has constantly been one of the bureaucratic bugbears for expanding access to safe abortion. On the one hand the country is faced with inadequate and inequitable access and on the other hand the process of registering the center for performing MTP's was, to say the least cumbersome and time consuming. The amendments to the MTP act address this issue and the registration process has now been decentralized.

Section 4 of the MTP Act defines settings where abortion may be provided legally as:

- A hospital established or maintained by the Government
- A place for the time being approved for purpose of this Act by the Government or a District Level Committee constituted by the government with the chief medical officer or district health officer as the chairperson. The district level committee shall consist of not less than three and not more than five members as may be specified from time to time.

Although a breakthrough in terms of policy, the decentralization and formation of district level committees has taken place as of now only in very few places in the country. Teething problems to form the committee have held up formation of these at most places and awareness within the system needs to be raised.

The Legal Status of the Medical Methods of Medical Termination of Pregnancy (Medication Abortion)

Medical methods for termination of pregnancy are recognized in an explanation in the amendments to the MTP Act. They are allowed to be administered up to 7 weeks (49 days) into the gestation by a registered medical practitioner as prescribed under Section 2 (d) and Rule 3, having access to a place approved by the Government under Section 4 (b) and Rule 5 of MTP Rules.

This means that even if a place is not registered an RMP as defined by the act can prescribe medical abortion here provided he/she displays a certificate proclaiming that he/she has access in terms of surgical backup to a place which is formally registered for MTP.

Documentation and Records

According to the MTP Regulation (Regulation 5) centers are required to maintain an Admission Register in the prescribed format (Form III) and preserved for 5 years. This is a secret document to be kept in safe custody. It is important for all practitioners of MTP to maintain good records and report them sincerely. Besides being a legal requirement there are several data gaps in our current databases which need to be filled. This data is significant for future planning, advocacy and monitoring progress.

Protection of Action Taken in Good Faith

The MTP Act (Section 8) protects the medical practitioner from suits or other legal proceedings for any damage caused or likely to be caused by anything done in good faith under the act. The important, thing to note is that to avail of the protection the provider has to be strictly within the framework laid down in the act and therefore the importance of sticking to the act in providing MTP services.

Further Changes

The MTP act stands out as an act which is wise, liberal and has the potential to relieve untold suffering to many women. Having said that, several lacunae which need to be addressed with further amendments still exist, e.g.:

- Requirement of two opinions for second trimester termination is now a formality and could be dispensed.
- A qualified extension of up to 22 weeks to accommodate terminations after prenatal diagnosis of birth defects simply because a large majority are diagnosed after this time.
- There is immense work to be done in terms of simplifying bureaucratic procedures to speed up the registration process.
- The subsection in Section 2 which elaborates on the failure of contraception specifies “married” couples who have a failure of contraception as eligible to undergo an MTP. The word married needs to be omitted.

These are only a few of the changes which need to be incorporated into the act.

CONCLUSION

We live in a structured society and it is important for each of us to appreciate and know as well as we can the rules that
govern our professional life. Not knowing the rules can hardly be termed as an excuse to break them.

We in India are fortunate to have a liberal law for provision of safe abortion. This inspired piece of legislature was in need of some changes and these came about as the MTP (Amendment) Act 2002. The Federation of Obstetrics and Gynecological Societies of India (FOGSI) was proud to play a significant role in the evolution of the amendments of the MTP act and will continue to be involved in updating and implementing the act.

Besides policy we also have to look at the ground realities which exist after policy is in place. Although the MTP act has greatly benefited the women of our country much work still remains to be done. We all have a role to play in achieving the goal of giving our mothers the freedom to make their choices safely. They deserve no less.
INTRODUCTION

With increasing awareness, information and education, male partner involvement in family planning and welfare is on the rise. Today, couples are able to discuss the family planning options amongst themselves and with their doctor and make a logical decision about the method of contraception both temporary and permanent.

Apart from condoms and spermicidal gels, with no reliable male contraceptive pill available, vasectomy remains one of the safest and the most effective permanent contraceptive method available and is a popular male option. As compared to tubal ligation done in females, vasectomy is easier, safer, does not require opening of the abdominal cavity, quicker and can be done as an outpatient office procedure. Under local anesthesia (LA) contraception is effective, reliable and reversible. In spite of all the advantages, it is less commonly performed than tubal ligations in most countries.

Population reports (2003) have found that apart from India and China, less than 1% of women in the developing countries rely on male sterilization as a contraceptive method. In India, the figure is 2%, Nepal 6% and China 8%. Male sterilization is a major family planning method (more than 40%) in the developed countries like United Kingdom (UK), United States of America (USA), Canada, Australia and New Zealand. The reason for the lower incidence in the developing countries could be gender bias, male dominance and misconceptions. Vasectomy is still shrouded with fear and ignorance and many associate this procedure with loss of virility.

With the improvements and evolution in techniques such as NSV Li et al., vasectomy has surpassed tubal ligations in some provinces of China. Also vasectomy reversal has better success rates than before. Technical success as evidenced by live spermatozoa in the ejaculate is achieved in greater than 95% of the patients operated by trained urologists. Studies suggesting increased incidence of prostatic cancer and also increased levels of antisperm antibodies have been discounted. All these factors have led to an increase in acceptance of vasectomy as a choice of voluntary permanent sterilization.

INDICATIONS

Vasectomy is indicated as a permanent sterilization method in couples or individual male who desires no further children. The concerned individual must be in a fit mental state and able to understand the consequences of his decision.

Eligibility Criteria [World Health Organization (WHO)—International Planned Parenthood Federation (IPPF)]

Contraindications

No permanent contraindication (irrespective of age and number of children).
Delay

Delay: Until condition is successfully treated or no longer exists
• Infection of operative area or acute systemic infections
• Signs and symptoms of sexually transmitted disease (STD)
• Filaria—elephantiasis
• Intrascrotal mass.

Special precautions: To be done in a facility well-equipped to handle complications
• Previous scrotal injury
• Large varicocele
• Large hydrocele
• Previous surgery for cryptorchidism
• Inguinal hernias
• Coagulation disorders.

Counseling and Preoperative Information

Males should be encouraged to undergo vasectomy as a permanent family planning procedure particularly if the female partner is weak, anemic, suffering from any systemic disease, heart problems or intra-abdominal adhesions and previous pelvic operations.

Vasectomy Procedure

• Complete preoperative counseling of patient.
• Perfect choice of technique and surgery without complications at a suitable center by a trained individual.
• Confirmation of success by semen examination showing sperm ejaculate.

The following information must be given to the patient:
• Vasectomy is a permanent male contraception method.
• It is done by a short simple office procedure under LA and does not require admission
• It does not mean castration
• It has no effect on masculinity, sexual activity, semen volume or general health.
• Millions of men have undergone this safe procedure in the last 50 years.
• Sterility does not occur immediately, hence other contraception like condoms must be used until ejaculate becomes sperm-free.
• There is a failure rate of 0.5%.
• Reversal is possible with 70% success rates in good hands.
• There is a 2% wound infection and hematoma rate.
• There is no long-term effect such as testicular or prostatic cancer.

Selection of Cases

Detailed history taking followed by local examination should be done. Local infection, scrotal problems, scrotal filariasis, hernias, hydrocele should be looked for. Psychiatric problem must be noted. Anemia, diabetes, blood pressure, recent cardiac diseases should be detected. Every attempt should be made to make vasectomy safe and avoid mortality, morbidity and subsequent discredit to the family planning program.

TECHNIQUE OF VASECTOMY

Anesthesia

Local anesthesia using up to 10 mL 2% lidocaine is injected using 24 gauge needle in the 2 cm area of the incision under the median raphe. Two to three milliliter of lidocaine is also injected along side the vas (into the vas sheath). Occasionally, general anesthesia (GA) may be used in extremely sensitive patients.

There are two methods of vasectomy:
1. Conventional vasectomy (CV)
2. Nonscalpel vasectomy (NSV)

Conventional Vasectomy

Steps

• A 1 cm incision is done in the skin in the median raphe upper end.
• The vas is rolled between the thumb and two fingers in the cord and palpated and brought under the skin incision.
• The vas is grasped with the Allis forceps. A longitudinal incision is made on the vas sheath and vas is pulled, dissected, exposed and held between the Allis forceps or towel clamp and brought out.
• A segment of vas is cut (0.5–1 cm) and both the ends tied. Various ligature methods are described. Hemoclips may be used or cauterization of the cut ends done. Fascial interposition (FI) may be done to prevent the cut ends from approximating. The distance between the two cut ends must be at least 2–4 cm. Too tight ligatures must be avoided as there may be chances of cut through.
• Hemostasis done, procedure repeated on the other vas and skin closure done (Figs 1A to D).

Nonscalpel Vasectomy

Steps

• The vas deferens is fixed under the skin at the median raphe using a specially designed ring forceps. It holds the vas extracutaneously and directly without injuring it.
• A dissecting forceps with a sharp-pointed tip similar to a curved mosquito forceps is used to puncture the skin directly overlying the vas contained within the ring forceps.
• The puncture hole is enlarged to twice the diameter of the vas deferens.
• The next step involves a delicate but firm grasping of the vas with the puncturing instrument and deliberately rotating the vas in a clockwise manner to make it bare and
The net result is a no incision, no stitch vasectomy with minimal dissection using only three instruments (vas fixation forceps, vas dissection forceps and a scissor) (Fig. 2) as compared to nearly 14 instruments required in CV.

The NSV is being implemented in India to help male sterilization and thus promote male participation in the family welfare program. Ensuring availability of this new technique in the peripheral rural areas will help increase the acceptance of male sterilization in the country. The project is being funded by the United Nations Fund for Population Activities (UNFPAs) who has contributed 9.15 crores. The Government of India will contribute in kind toward providing centers for training and making available necessary infrastructure at the training sites.

**Advantages of Nonscalpel Vasectomy over Conventional Vasectomy**

- It takes less time (about 10 minutes)
- Causes faster recovery
- Less painful
- Less chances of bleeding and hematoma formation
- Only three instruments required
- No stitch required.
  However, some training and special instruments are needed.

Complications include pain, swelling, discomfort, bleeding and hematoma formation. Infections may occur, sperm granuloma may result in a palpable lump. Antisperm antibodies have been demonstrated in 40–60% of men.

**Fig. 1A to D:** Step of conventional vasectomy. (A) Incisions on the skin, (B) The sheath of the vas is cut open, (C) A portion of the vas is removed, (D) The vas is ligated at the cut ends

**Fig. 2:** Steps of nonscalpel vasectomy
undergoing vasectomy. Failure of vasectomy may occur in 0.1–1.2% of the cases.\textsuperscript{5,6} A small percentage of people (less than 10%) have chronic testicular pain after vasectomy.\textsuperscript{7}

**Postoperatively:** About 15–20 ejaculates contain sperms and 2–3 months are required to become sperm-free during which time alternative contraceptive method must be used.

### RECENT DEVELOPMENTS

The two main components of vasectomy are isolation of the vas deferens from the scrotum and subsequent vas occlusion. However, more than 30 different combinations of vas occlusion (Figs 3A to H) have been described.\textsuperscript{8} Poor quality studies, heterogeneous study designs and conflicting results have made it difficult to determine which are the most effective.\textsuperscript{8} The most common technique especially in low resource settings is future ligation with excision of a small segment of vas.\textsuperscript{8} Recent evidence from Asia suggests that 95% of all vasectomies in India are done using ligation and excision.\textsuperscript{10} In contrast, data available indicates that only 18% of the vasectomies in the US are done using this technique.\textsuperscript{11} Although vasectomy has traditionally been thought to have overall failure rates of 1–3%,\textsuperscript{12–14} recent research indicates higher failure rates for ligation and excision.\textsuperscript{15–17} A meeting of vasectomy experts held in December 2003 came to the following conclusion:

- Ligation and excision of a small segment of the vas lumen is also more effective than ligation and excision alone.
- Recent evidence indicates that cautery plus FI is more effective than ligation and excision and FI but FI is technically challenging.

**Fascial Interposition**

This is a new technique in which the sheath covering the vas is pulled over one-severed end and the sheath is closed to create a natural tissue barrier (Figs 3A to H). The testicular end of the vas lies within the sheath and the prostatic end lies outside. Many practitioners prefer it the other way round.

### Review of Literature

Review of literature is based on author’s conclusion after extensive Medline, Embase review, textbooks and book chapters evaluation.

**Vasectomy Surgical Techniques\textsuperscript{18}**

Current evidence supports NSV as the safest surgical approach to isolate the vas when performing a vasectomy. Adding FI increases effectiveness beyond ligation and excision alone. Occlusion effectiveness appears to be further improved by combining FI with cautery.

### Scalpel versus Nonscalpel Vasectomy\textsuperscript{19}

The nonscalpel approach to the vas, resulted in less bleeding, hematoma, pain and infection, as well as shorter operative time than the traditional incision technique. Although no difference in effectiveness was found between the two approaches, the sample sizes might have been too small to detect the differences. Additional well-conducted randomized trials are needed.

### CONCLUSION

- Vasectomy is a simple method of permanent sterilization in males and is gradually gaining more acceptance.
- Nonscalpel vasectomy is the new method promoted by the Family Planning Association of India (FPAI)—it is quicker, safer and an office procedure which can be done under LA. However, it requires a trained surgeon.
- Failure rates are directly related to the experience of the operating surgeon.
- Ligation, excision of a segment and vas occlusion with cautery seems to be the best combination.
- Fascial interposition is a new technique which reduces failures.
- Making vasectomy absolutely safe with minimum complication and failure rate will boost the family planning program.

General Gynecology
## INTRODUCTION

Abnormal uterine bleeding is defined as any bleeding from the uterus which is not normal cyclical menstruation. It is a common clinical problem with many different causes. However, with a sound knowledge of menstrual physiology and a scientific approach to differential diagnosis, we can evaluate and manage the problem with confidence.

## MENSTRUAL PHYSIOLOGY

The typical menstrual cycle has two phases: (1) proliferative and (2) secretory. The proliferative phase is characterized by a predominance of estrogen over progesterone and a buildup of endometrium. The secretory phase begins after ovulation triggers progesterone production. This phase is marked by a reaction to the combination of estrogen and progesterone and stabilization in the thickness of the endometrium.

Menstrual bleeding occurs after secretion of estrogen and progesterone tapers off. Early during menses, thrombin plugs restrain blood loss, but later, vasoconstriction of the spiral arterioles is responsible for hemostasis. When ovulation does not take place, progesterone levels do not rise; therefore, typical cyclic withdrawal of estrogen and progesterone cannot occur.

Normal menstrual cycles are characterized by a cycle length of 28 days (±7 days), a duration of flow of 4 days (±2 days), and a blood loss of 40 mL (±20 mL) (Fig. 1).³

### Causes

Several types of abnormal uterine bleeding² are described in Table 1.
Whenever a woman presents with abnormal menstrual bleeding the differential diagnosis should be kept in mind as shown in Table 2.

### Diagnostic “Rules”

The list of differential diagnostic considerations in abnormal uterine bleeding is extensive, but systematic consideration of each of the five categories has led to our set of six diagnostic “rules”. Following an algorithm (Flow chart 1) of these simple diagnostic rules will enable the gynecologists to come to a diagnosis with minimum testing and minimum interventions.

**Rule No. 1: Consider Pregnancy**

All women of reproductive age should have a urine or serum pregnancy test.

**Rule No. 2: Consider Coagulopathy**

All adolescents with menorrhagia severe enough to require hospitalization or significantly reduced hemoglobin levels (to < 10 g/dL) should undergo evaluation for coagulopathy. Disorders of both platelet number and function may cause menorrhagia. von Willebrand disease, a defect in platelet adhesion and a deficiency of factor VIII, is the most common bleeding disorder, affecting about 1% of the population. Diseases causing thrombocytopenia include idiopathic thrombocytopenic purpura, leukemia and aplastic anemia. In adolescents, the prevalence of a primary coagulation disorder requiring hospitalization for abnormal uterine bleeding ranges from 3% to 20%.

**Rule No. 3: Consider Pelvic Lesions**

In women with evidence of ovulation, abnormal uterine bleeding should prompt suspicion of benign pelvic lesions. These patients should undergo thorough endometrial evaluation for pelvic lesions when there is no obvious alternative cause of abnormal bleeding.

**Rule No. 4: Consider Malignancy**

Without exception, perimenopausal or postmenopausal women with abnormal uterine bleeding should undergo endometrial evaluation. Until malignancy has been ruled out, it should be considered the cause. About 20–25% of cases of endometrial carcinoma occur before the menopause.

**Rule No. 5: Consider Hypothyroidism**

Hypothyroidism is an uncommon, although important, cause of metrorrhagia or menorrhagia. Women with unexplained severe menorrhagia should undergo thyrotropin assay.

**Rule No. 6: Consider Dysfunctional Uterine Bleeding**

Dysfunctional uterine bleeding is a diagnosis of exclusion. In the vast majority of cases, it is secondary to anovulation, which is more common at the extremes of reproductive age (i.e. during the postmenarchal and perimenopausal periods). Chronic anovulation may also be associated with thyroid or prolactin disorders, premature ovarian failure, adult-onset
CHAPTER

Approach to Abnormal Uterine Bleeding

congenital adrenal hyperplasia, or polycystic ovary syndrome. Some common causes of hypothalamic anovulation are weight loss or gain, eating disorders, stress, chronic illness and excessive exercise. Women with chronic anovulation that is not attributable to any of these causes are considered to have idiopathic chronic anovulation.

Anovulatory bleeding can be thought of as estrogen breakthrough bleeding. This type of bleeding is related to the levels of estrogen stimulating the endometrium. For example, high levels of estrogen for prolonged periods result in amenorrhea followed by acute intermittent heavy bleeding, and continually low levels of estrogen availability result in intermittent spotting.

EVALUATION

A logical sequence of evaluation for abnormal uterine bleeding can be constructed on the basis of the preceding information.

STEPS FOR EVALUATION

1. Complete history taking with age and complaints of the patient
2. Physical examination (clinically and pelvic examination)
3. Diagnostic testing (CBC, urine pregnancy test, thyroid assay)
4. Pap smear and cervical cultures
5. Endometrial evaluation
6. Hysteroscopy
History Taking

The specifics of the bleeding pattern should be elicited on history taking. The frequency, duration and severity of flow should be ascertained. It is also critical to determine if the bleeding is acyclic or cyclic, the latter being more consistent with ovulation. Other important considerations include patient age, sexual history (which determines risk for sexually transmitted diseases), previous gynecologic disease, likelihood of pregnancy, use of medications or hormonal contraceptives and the presence of chronic medical problems.

Physical Examination

Evidence of systemic diseases; signs and symptoms of hypothyroidism, liver disease, hyperprolactinemia, eating disorders and coagulopathies warrant special attention. A thorough pelvic examination, including a Pap smear, is essential. If indicated by history or physical findings, cervical cultures for Neisseria gonorrhoeae and Chlamydia trachomatis should be obtained. Benign lesions of the uterus may be obvious. For example, uterine myomata may result in an irregularly contoured, enlarged uterus that is palpable on bimanual examination.

Diagnostic Testing

In most cases, laboratory evaluation is limited to a complete blood cell count. However, all women of reproductive age who have abnormal uterine bleeding should have a urine or serum pregnancy test. Other tests are done only if indicated by the results of history taking and physical examination.

Endometrial Evaluation

Further investigation of abnormal uterine bleeding is guided primarily by the patient’s age. Adolescents who are not pregnant do not require additional workup.

More controversial is evaluation of abnormal bleeding in nonpregnant women who show no obvious cause (i.e. no abnormal findings on pelvic examination, no evidence of systemic disease and no use of medications that interfere with menses). Investigators disagree over two issues: (1) whether all patients need further endometrial testing and (2) whether this testing should include visualization of the endometrial cavity (i.e. ultrasound) or sampling of the endometrial tissue.

Most investigators recommend that further evaluation of abnormal uterine bleeding in nonpregnant women be based on risk for endometrial neoplasia. Therefore, women who are under 35 years of age and have no identifiable risk factors for neoplasia can be assumed to have dysfunctional uterine bleeding and treated accordingly. However, perimenopausal and postmenopausal women and women who are younger than 35 years of age but have a history of chronic anovulation or obesity are considered at high risk, and endometrial biopsy or transvaginal ultrasound is required to rule out endometrial hyperplasia or cancer. Some investigators are firm in the more conservative recommendation that any woman over 35 years of age with abnormal uterine bleeding undergo endometrial evaluation.

Endometrial Biopsy

Sampling techniques using small, flexible, disposable devices are adequate for obtaining endometrial tissue. To ensure accuracy, the procedure must be done before any hormonal treatment is given, and multiple areas of the endometrium must be sampled (Figs 3A to C).

Most endometrial biopsy results fall into one of four categories (Table 3). The presence of atypia is the most important risk factor for development of cancer. Carcinoma has been found to develop in 25% of patients with atypia but only 2% of patients without atypia. All patients with atypia should therefore be referred for gynecologic evaluation.

Patients who have hyperplasia but no evidence of atypia should be treated with progestins, and surveillance endometrial biopsy should be done every 3–6 months. The presence of normal secretory endometrium on biopsy indicates that the patient is having ovulatory cycles. This finding should raise suspicion that the bleeding is from a cause other than anovulation (e.g. a benign pelvic lesion).

Before in-office biopsy is done, pregnancy and significant cervical stenosis must be ruled out. Patients with significant stenosis may be better evaluated with use of transvaginal ultrasound.

Endometrial Aspiration

Endometrial aspiration can be done with the help of devices, like Pipelle® curette, Sharman’s curette, Gravlee jet washer, Isaac cell sampler, Vabra® aspirator, etc. The diagnostic accuracy of endometrial aspiration using Pipelle® device is 92–98% when compared with subsequent D&C. Since no dilatation of the internal os is required prior to insertion at the time of endometrial aspiration, the procedure can be performed as an outpatient procedure without any requirement of anesthesia. Following the procedure, the endometrial sample obtained is sent for histopathological examination (Figs 4A and B).

Table 3: Common findings on endometrial biopsy

- Proliferative, secretory, benign, or atrophic endometrium
- Simple or complex (adenomatous) hyperplasia without atypia
- Simple or complex (adenomatous) hyperplasia with atypia
- Endometrial adenocarcinoma.
### Approach to Abnormal Uterine Bleeding

#### Ultrasound

The use of transvaginal ultrasound (Fig. 5) in women at high risk for endometrial neoplasia is gaining popularity because it is an inexpensive, noninvasive and convenient way to indirectly visualize the endometrial cavity and measure endometrial thickness. This technique has been studied most extensively in postmenopausal women, but investigators are beginning to examine its use in premenopausal women as well. A recent meta-analysis of uterine bleeding in postmenopausal women concluded that the sensitivity of transvaginal ultrasound compares favorably with that of endometrial biopsy. In this population, a threshold of 5 mm of endometrial thickness was associated with 96% sensitivity for cancer detection and 92% sensitivity for detection of endometrial disease (e.g. cancer, hyperplasia, polyps). This false-negative rate of 8% compares favorably with the 5–15% false-negative rate with endometrial biopsy.

Evaluation of abnormalities in premenopausal women who have an endometrial thickness greater than 5 mm is controversial. About 10% of such patients have hyperplasia and about 40% have myomata or polyps.

Nondirected outpatient endometrial biopsy may miss a significant percentage of benign endometrial lesions. For this reason, some clinicians recommend proceeding immediately to a more directed endometrial evaluation, such as saline-infusion sonohysterography or dilation and curettage with hysteroscopy. Others perform an endometrial biopsy and, if...
results are normal, treat for presumed dysfunctional uterine bleeding. Patients for whom medical therapy fails are then evaluated with directed biopsy.

Hysteroscopy
Hysteroscopy is the gold standard for evaluation of endometrial cavity. It provides direct visualization of the cavity (Fig. 6). It can be used for both diagnostic and operative purposes for directed biopsies and excision of polyps.

Saline Infusion Sonography
Saline infusion sonography involves direct extension of uterine cavity with saline to enhance visualization of the endometrial surface. It is a noninvasive method to diagnose endometrial polyps and submucous myomatas (Fig. 7).

CT-scan and MRI
CT-scan and MRI primarily used in patients with suspected malignancy or adenomyosis.

TREATMENT OPTIONS
Complications of Pregnancy
If beta-hCG is positive, a careful pelvic examination must be performed and USG should be done to determine the possibility of ectopic pregnancy, threatened abortion, inevitable or missed abortion. Any patient who is hemodynamically
unstable and bleeding heavily may require surgical interventions like D and C or laparoscopic surgery for ectopic. Antimicrobial prophylaxis is a must. If any signs of infection are present, a broad spectrum coverage should be given. Woman with missed or incomplete abortion who is stable and not bleeding heavily may be treated with misoprostol.

**Benign Pathology**

Fibroids are the most common uterine neoplasms. They present with abnormal uterine bleeding mostly menorrhagia. Commonly done surgical procedures for treatment are: myomectomy, hysterectomy or myolysis. Polyps are generally endometrial lesions which tend to be asymptomatic. If symptomatic they usually cause premenstrual or postmenstrual spotting. Polyps are removed by operative hysteroscopy.

**Malignant Pathology**

Endometrial cancers are rare. They occur in older age after 40 years of age. They must be suspected in postmenopausal women. Treatment—total abdominal hysterectomy with bilateral salpingo-oophorectomy is the standard therapy. The need for postoperative radiation therapy depends on the stage. Treatment of cervical carcinoma depends on the staging—surgical resection, chemotherapy, radiation or combination.

**Systemic Diseases**

- **Disorders of coagulation:** von Willebrand disease is the most common inherited bleeding pathology. Test performed to diagnose are factor VIIIC activity, vWF antigen, platelet function tests and bleeding time. OCPS, desmopressin, and antifibrinolytic agents are treatment options.
- **Endocrinopathies:** Endocrine disorders can cause anovulation and produce an environment of unopposed estrogen. Hypothyroidism and hyperprolactinemia are common disorders. Bromocriptine or surgical resection of macroadenoma pituitary may relieve hyperprolactinemia. Thyroid replacement therapy may be necessary for hypothyroidism.
- **Liver failure:** Decreased metabolism of estrogen may lead to endometrial glandular and stromal break down causing endometrial hyperplasia. If possible underlying liver disease it should be treated. Progesterone therapy may be beneficial.

**Drug Induced**

Drug induced various medications like antipsychotic, OCPS, anticoagulants, digitalis, phenytoin, Depo-provera may cause abnormal uterine bleeding.
Intrauterine Devices
Copper intrauterine contraceptive devices (IUCDs) may increase average monthly blood loss. It can be treated by nonsteroidal anti-inflammatory drugs (NSAIDs).

Dysfunctional Uterine Bleeding
Dysfunctional uterine bleeding (DUB) is the diagnosis of exclusion. It is usually treated by long-term OCPS, HRT, Danazol, NSAIDs or antifibrinolytic agents (Table 4).

**Intrauterine Devices**

Copper intrauterine contraceptive devices (IUCDs) may increase average monthly blood loss. It can be treated by nonsteroidal anti-inflammatory drugs (NSAIDs).

**Dysfunctional Uterine Bleeding**

Dysfunctional uterine bleeding (DUB) is the diagnosis of exclusion. It is usually treated by long-term OCPS, HRT, Danazol, NSAIDs or antifibrinolytic agents (Table 4).

</tbody>
</table>

choice of treatment depends on whether bleeding is acute or chronic. When bleeding is acute, the first step is to determine if the woman’s condition is hemodynamically stable. A patient with signs of hypovolemia should undergo volume resuscitation, be hospitalized, and be given high-dose intravenous estrogen. The estrogen promotes rapid endometrial regrowth over the denuded epithelial surfaces. If this treatment fails, most clinicians proceed to dilation and curettage, which quickly controls bleeding.

The hemodynamically stable patient with acute heavy bleeding should also be treated with estrogen. The most convenient method of estrogen administration is use of low-dose monophasic oral contraceptives. Nausea and vomiting from the high doses of hormones can be minimized by adding an antiemetic agent such as promethazine (Anergan, Phenergan) or chlorpromazine hydrochloride (Thorazine).

After finishing the course of oral contraceptives, the patient typically experiences a heavy, crampy period. Patient should continue to take low-dose oral contraceptives for at least another 3 months and then undergo re-evaluation to determine whether treatment for chronic bleeding is indicated.

In patients with an absolute contraindication to estrogen (e.g. a 36-year-old smoker with history of deep vein thrombosis), some clinicians use high-dose progestins to control bleeding. There are no randomized, placebo-controlled trials to support this practice.

Treatment of patients with chronic recurrent bleeding is based on their reproductive desires. Patients who want birth control can use low-dose monophasic oral contraceptives. If contraception is not desired, use of cyclic progestins for the first 10 days of each month is the treatment of choice (Table 4). Patients wishing to become pregnant are candidates for clomiphene citrate (Clomid, Milophene, Serophene).

If any of these regimens fails to control what has been assumed to be dysfunctional uterine bleeding, other diagnoses, specifically structural abnormalities of the endometrium, must be considered. Often, endometrial biopsy does not detect reproductive tract abnormalities such as endometrial polyps and submucosal fibroids. In this situation, further evaluation may be performed with endovaginal ultrasound or saline-infusion sonohysterography. The latter procedure involves instilling fluid into the uterus during an endovaginal ultrasound examination to enhance image resolution. This purely diagnostic procedure can be done in the office using only local anesthesia, but skill in its performance and interpretation is required for consistently accurate results.

For patients at high risk for complications of anesthesia, sonohysterography is a reasonable option. Patients who are good surgical candidates, however, may opt to proceed directly to a dilation and curettage with hysteroscopy, which allows simultaneous diagnosis and treatment.

In the few cases in which dysfunctional uterine bleeding does not respond to any of the management options described, hysterectomy or endometrial ablation can be done. A hysterectomy is indicated when a patient has associated pelvic abnormalities such as leiomyomas and does not wish to preserve fertility. Endometrial ablation is a less costly, safer alternative to hysterectomy for women with no uterine lesions. Ablation can be performed on an outpatient basis with a laser or electrocautery device (roller ball).

CONCLUSION

The approach to diagnosis of abnormal uterine bleeding is guided by a sound knowledge of menstrual physiology and differential diagnosis. Often, simple anovulation is the underlying problem, although the possibility of pregnancy, endometrial hyperplasia with atypia, or benign reproductive
tract disease must be considered. In the majority of cases, abnormal uterine bleeding can be fully evaluated and effectively treated medically without the need for gynecologic referral.

REFERENCES

INTRODUCTION

Uterine leiomyomas (fibroid/myoma/leiomyofibroma) are the most common benign, monoclonal tumors of the smooth muscle cells of the myometrium in women, affecting 20–50% of reproductive age population. Examination of hysterectomy specimens by serial sectioning at 2 mm intervals suggests prevalence of 77%. Despite their prevalence, the disease has remained enigmatic, with the natural history and progression incompletely understood. Recent research on molecular biology of myomas has enabled us to understand better the pathophysiology of this tumor.

EPIDEMIOLOGY

The frequency of clinically obvious fibroids is an underestimation because majority are asymptomatic. The incidence of pathologically diagnosed fibroids increases steadily with age. The chance of being diagnosed with fibroids increases with age until about 50 years and then declines sharply.

There are significant differences in prevalence of fibroid between women of different racial and ethnic background. A carefully conducted case-control study found self-reported African-American heritage to be associated with a relative risk (RR) of fibroids of 9.4 compared to white women. Both Hispanics and Asians had risks similar to whites. Fibroids are diagnosed at a younger age, are more often multiple and tended to be larger in African-Americans.

Fibroids are 2–3 times more frequent when there is a family history. A Japanese study examined the prevalence of fibroid in first degree relatives of women undergoing surgery for fibroids. Thirty-one percent of women undergoing fibroid surgery reported a first degree relative with fibroids, as opposed to 15% of controls. The risk also increases as age at menarche falls.

Oral contraceptives (OCs) are protective with the RR decreasing in a dose-dependent fashion to the duration of OC use. However, exposure of OC at age 13–16 years has a higher risk. Starting OCs at a younger age could be a marker for other risk factors for fibroids rather than a cause itself. Depot medroxyprogesterone has been associated with protection whereas tubectomy slightly increases the risk.

For the majority of postmenopausal women with myomas, hormone therapy will not stimulate uterine growth. If the uterus does grow, it is more likely related to the dose of progesterone than estrogen.

Obesity increases while smoking diminishes the risk of fibroid probably due to higher and lower endogenous estrogen levels respectively. The Nurse Health Study II (NHS II) showed an increased risk for fibroid with increasing BMI. Risk of myoma increased 21% with each 10 kg increase in body weight. Although red meat increases and green vegetables decrease the risk, dietary interventions are not protective.

Several studies have shown a protective effect of pregnancy on the development of fibroids, with parity decreasing the risk of fibroids up to fivefold. However, these numbers may be deceptively high, given the known decrement in fertility attributable to fibroids. Age at first pregnancy is not a risk factor. A longer interval from the last child birth increases the risk. Childbearing during the mid-reproductive years (age 25–29 years) provides the greatest protection against myoma...
development. The increased number of menstrual cycles is the risk factor in nulliparous and less parous women. It is not clear whether fibroid is a cause or consequence of infertility. Recently, the association with nulliparity and infertility were found only with submucous tumors.11

A recent study demonstrated an intriguing link between diastolic blood pressure and fibroids.12 It is suggested that elevated blood pressure could cause injury or cytokine release in the uterine smooth muscles that promotes fibroid growth. The increased risk is related with degree and duration of hypertension.

There is positive association between fibroid and pelvic infections. A history of pelvic inflammatory disease increases the risk of fibroids, with the risk increasing with the number of infectious episodes. It seems that the intrauterine irritation may contribute to fibroid growth.

**PATHOLOGY**

Leiomyoma, essentially a smooth muscle tumor, contains variable amounts of fibrous tissue and collagen matrix. The latter is responsible for the misnomer “fibroid.” They arise from the body of the uterus in majority of cases, but may be cervical (3.8%). They may be single but are more often multiple. They originate from the uterine muscle layer and may remain intramural or become subserous or submucous. Subserous fibroids may become pedunculated. Rarely, they lose their uterine attachment gaining new blood supply from another organ (wandering/parasitic fibroid). Arising from lateral uterine wall they may grow into a broad ligament tumor.

Submucous fibroids comprise just 5% of all tumors but are often symptomatic. They may also be pedunculated, distend the cervical canal or may prolapse through the cervix. Rarely, they can cause inversion.

**Macrosopically,** fibroids are usually spherical, well circumscribed, white, firm lesion(s) that protrude from the cut myometrium. The cut surface has a lighter color than normal myometrium and has a whorled appearance with intersecting fascicles of smooth muscle bundles. A typical intramural fibroid is separated from the adjacent normal myometrium by a thin layer of connective tissue—the so-called false capsule (there is no true capsule). Small nutrient arteries penetrate the capsule although a single larger artery provides the major blood supply.

**Microscopy:** Leiomyomas are made-up of interlacing bundles of elongated eosinophilic smooth muscle cells with pink fibrillar cytoplasm and blunt ended cigar shaped nuclei that have an even chromatin pattern and inconspicuous nucleoli. Occasional mitosis is seen. These cells are surrounded by varying amounts of collagenous fibrous connective tissue containing rather thick walled blood vessels. Fibrous tissue cells have less cytoplasm, are without fibrils and the elongated spindle shaped nuclei have more pointed ends.

The term cellular leiomyoma is used when the density of the smooth muscle cells is significantly greater than usual but there are no atypical features such as increased mitotic count, abnormal mitosis, coagulative necrosis or cellular pleomorphism. These latter features characterize the classical leiomyosarcomas that show a more variegated cut surface and a more invasive irregular margin. Lesions intermediate between classical leiomyoma and leiomyosarcoma with unpredictable clinical outcome are called smooth muscle tumors of uncertain malignant potential.

**Degenerative Changes**

Majority lack clinical significance and occur secondary to circulatory alterations, postmenopausal atrophy or infection. A most acute form is red/carneous infarction, causing pain and localized peritoneal irritation, most often in mid pregnancy.

The risk of sarcomatous change is 0.1%, but majority of these are symptomatic with pain, malaise, vaginal bleeding and postmenopausal enlargement. Genetic differences between myomas and leiomyosarcomas indicate that they most likely have distinct origins and that leiomyosarcomas do not result from malignant degeneration of myomas.13

### ETIOPATHOGENESIS

Despite the prevalence of leiomyomas, relatively little is understood about their development and growth. Unlike the quiescent myometrium, leiomyoma exhibits elevated rates of mitotic activities and S-phase fractions.14 Growth of these tumors is believed to depend on ovarian hormones. These hormones may exert their growth stimulatory effects through some intermediate elements such as cytokines and growth factors. Estrogen and progesterone may regulate gene expression of these cytokines and growth factors which in turn modify the transcription of other genes.

**Cytokines and Growth Factors**

The abnormal production of cytokines and growth factors results in increase in cell proliferation, accumulation of extracellular matrix or combination of these phenomena.

Another potential mechanism, decreased apoptosis is responsible for development of fibroid. Bcl-2 protein—an apoptosis inhibiting gene product is abundantly expressed on fibroid and progesterone upregulates this Bcl-2 protein.15

However, estrogen has a downregulatory effect. GnRH antagonist up regulates apoptosis.

Each tumor results from a single progenitor smooth muscle cell which undergoes a somatic mutation (Step I). The subsequent growth occurs by clonal expansion of the mutated myocyte (Step II). Multiple myomas within the same uterus are clonally unrelated. The initiator(s) of Step I are unknown but genetic predisposition and ovarian hormones may have a role in both formation and growth of fibroids. A large number of growth factors (Table 2) have been identified which cause tumor expansion (Step II). The pathobiology involves alterations in:

a. Smooth muscle cells (SMC): Proliferation and differentiation.
b. Fibroblast (proliferation) and extracellular matrix (deposition): Overexpression of collagen, fibronectin and glycosaminoglycans contributes to the formation and growth of the tumor.
c. Angiogenesis: To support growth, proliferation and migration of endothelial cells.

Fibroids have increased levels of both Estrogen (E) and Progesterone (P) receptors. The SMCs show both higher mitosis and decreased apoptosis. Both E and P are important. Estrogen does not induce mitosis in follicular phase; instead it maintains a differentiated state and essentially benign nature of the tumor. Increased mitosis seen during luteal phase suggests P as mitogen. Myomas show higher mitotic activity in women treated with P compared to women treated with E and P or in women receiving no hormones. Progesterone may also expand tumors by down regulating apoptosis, by increasing expression of bcl-2 protein (an apoptosis inhibitor).

Although blood levels of estrogen and progesterone are similar in women with or without clinically detectable myomas, levels of estradiol within myomas are higher than in normal myometrium. De novo production of estrogen within myoma tissue is suggested by increased level of aromatase, an enzyme that converts androgens to estrogen. Low levels of enzyme that convert estradiol to estrone have been found in myoma cells and may promote accumulation of estradiol within the cells, leading to upregulation of estrogen and progesterone receptors and myoma growth.

**Genetics (Flow Chart 1)**

Fibroid is not a single gene disorder. However non-random chromosomal changes such as translocations, duplications and deletions have been identified in nearly 40% of tumors
by cytogenetic analysis. Abnormal myoma when compared with normal myoma are generally more cellular, have a greater mitotic index and lower DNA content and also fail to produce a decrease in DNA content after GnRH agonist therapy. The remaining 60% of myomas, which are chromosomally normal, suggests that genetic aberrations may be submicroscopic for these tumors.

In examining fibroid with abnormal karyotypes certain correlations between tumor genotype and clinical phenotype have been observed. Only 12% of submucosal fibroids have chromosomal rearrangements, followed by subserosal (29%) and intramural (35%). However, in spite of lower frequency of karyotypic rearrangements, submucosal fibroids are highly symptomatic. Thus far, no correlation has been established in fibroid between type of cytogenetic aberration and patient age or parity.

Several genes have been implicated in the molecular pathogenesis of leiomyoma including the sex-steroid associated genes, estrogen receptor α, estrogen receptor β, progesterone receptor A, progesterone receptor B, growth hormone receptor, prolactin receptor, extracellular matrix gene and collagen gene. Chromosomal rearrangements in fibroid have been noted in the High Mobility Group I Proteins including those encoded by HMG 2A (formerly HMG 1C) and HMG 1A (formerly HMG 1Y). High levels of these closely related low molecular mass proteins are detected in fibroid but not in the adjacent myometrium.

### CLINICAL FEATURES

Majority of fibroids are asymptomatic. Around 20–50% of fibroids produce symptoms (Table 3).

The most common symptom is menorrhagia reported by 30% of women with fibroids.

### Bleeding

Irregular bleeding is not characteristic of myoma and should be investigated to rule out endometrial disease. Pedunculated submucous tumors with infection or surface ulceration can however produce acyclical bleeding. Submucous myomas are the most likely to cause menorrhagia. Some studies suggest that only 40% hysterectomy specimens done for fibroid with menorrhagia have submucous tumors.

### Infertility

The conviction that myoma cause infertility derives mostly from observational studies in which about half of patients who undergo myomectomy subsequently conceive. None of these studies are controlled. Around 25–40% of women with fibroids are infertile, but other causes of infertility are present in majority of cases. Submucous fibroids decrease fertility: pregnancy rate decreases by 70% and their removal increases fertility to baseline rates. Some recent studies of women undergoing IVF suggest that even intramural tumors may be contributory.

### Pelvic Pain/Pressure

Uncomplicated myomas do not produce pain. The pelvic-abdominal discomfort, often called pressure depends on fibroid location. Urinary symptoms arise from anterior myomas (frequency and rare retention), while posterior ones can cause low backache, rectal tenesmus or constipation. Cervical and broad ligament tumors produce no menstrual disturbances but only pressure symptoms including ureteric obstruction. Some large tumors may be discovered by the patient herself.

Exceptionally fibroids produce acute pain due to torsion (subserous tumors/regeneration/infection). Attempted expulsion of pedunculated submucous tumor through cervix may cause uterine cramps/dysmenorrhea.

In premenopausal women, rapid uterine growth almost never indicates presence of uterine sarcoma. Most women found to have uterine sarcoma are clinically suspected of having a pelvic malignancy.

### Problems during Pregnancy

Very rarely does the presence of a fibroid during pregnancy lead to an unfavorable outcome. Possible effects of fibroid on pregnancy are shown in Table 4.

**Effect of pregnancy on fibroids:** Contrary to expectation, majority of fibroids remain unchanged/decrease in size. Only 20–30% fibroids increase in size; and the increase is no more than 25% in volume and occur mostly in first trimester.

</tbody>
</table>

**Abbreviations:** IUGR, intrauterine growth restriction; PPH, postpartum hemorrhage.
There is no relationship between initial fibroid volume and fibroid growth during gestational periods. Most fibroids remain uncomplicated but 10% undergo red degeneration.

Anemia is the major consequence of menorrhagia. Rarely secondary polycythemia is possible (elaboration of erythropoietin by tumor tissue).

Palpation of an enlarged, firm, irregular, non-tender uterus with some mobility by abdominal and vaginal examination gives away the diagnosis in 95% of cases. Submucous myoma may cause symmetric uterine enlargement; subserous pedunculated tumor may mimic adnexal mass. Consistency may be altered by degenerative changes and mobility may be restricted by coexistent disease (e.g. endometriosis).

The most common differential diagnosis includes pregnancy, adenomyosis and ovarian tumor.

INVESTIGATIONS

Investigations confirm the diagnosis and may decide mode of treatment (Table 5). Ultrasonography (USG) assesses size(s), location(s), interval growth, adnexal anatomy and excludes hydronephrosis. Submucous myoma often requires saline-infusion sonography, hysteroscopy or MRI for definitive diagnosis. Differential variegated echogenicity in the myometrium is characteristic of fibroids; cystic/calcific degeneration may also be revealed. Transvaginal sonography (TVS) evaluates the endometrial cavity better and it is the most readily available and least costly technique and may be helpful for differentiating myomas from other pelvic conditions.

Laparoscopy is useful if uterus is not larger than 12 weeks of gestation and there is associated infertility or pelvic pain. MRI represents the most accurate method to determine size, location and route of removal and with low inter-observer variability in interpretation. It can differentiate fibroid from adenomyosis (sensitivity 64%, specificity 88%) and was superior to TVS (sensitivity 59%, specificity 79%). For most indications, the extra cost is not justified and USG should be the initial evaluation.

The preoperative diagnosis of leiomyosarcoma may be possible with total serum lactate dehydrogenase (LDH), LDH isoenzyme 3 and gadolinium-enhanced MRI.

CONCLUSION

Despite the frequency and the morbidity they can cause, fibroids remain a frontier for gynecologic investigations. New research into basic biology, especially the role of growth factors and genetic mutations hold promise for new therapeutic options.

REFERENCES

Fibroids are the most common neoplasm of the uterus and therefore understanding appropriate therapy for these is important. Newer researches are opening better avenues for therapy in this condition and as we progress further reappraisal and understanding of the cellular mechanisms and growth influences of fibromyomas is essential to better treat our patients.

More than 50% of women have leiomyomas and most of the times they are asymptomatic. If surgical specimens are serially sectioned, about 77% of women who come to hysterectomy will have myomas, many of which are occult. Many a times fibroids are incidental findings on clinical evaluation making us wonder whether treating them is mandatory.

Advanced age of marriage and late pregnancies have increased the need of conservatively managing fibroids either surgically or medically. Also availability of various treatment modalities (Table 1) has increased the need to understand the advantages and disadvantages of these and their appropriate place in the given clinical situation. Increased awareness and availability of diagnostic modalities has also increased the incidence of myomas being diagnosed, not always mandating treatment and therefore could require expectant management. It is therefore essential to tailor appropriate treatment exclusively to the presenting clinical situation basing the decision on sound evidence.

**TREATMENT FOR MYOMAS MODALITIES**

**Expectant Management**

This consists of serial history taking and clinical evaluation at regular intervals. The initial evaluation could be undertaken at 3 or 6 monthly interval to determine the rate of growth. Yearly follow-up intervals can be undertaken if the tumors are documented to be stable or slow growing after 1–2 years of observation.

Women with menorrhagia, dysmenorrhea, pelvic pain and pressure symptoms can be treated with nonsteroidal anti-inflammatory drugs (NSAIDs), combination pills (low-dose) and progestins after ruling out endometrial pathology with suitable diagnostic modality.

**Medical Management**

Fibroids are tumors sensitive to hormonal influences. Based on this proposition many hormonal and non-hormonal modalities of therapy have been used. Fibroids are estrogen sensitive tumors growing at a slow rate. Sometimes they grow faster and this rate of growth is semi-quantitatively linked to

Girija Wagh, Sanjay Gupte
(Chapter updated by Rekha Rani)
the number of estrogen and progesterone receptors (PRs). Rapid growth raises the possibility of malignant change within the tumor although this is extremely rare. It is clear that hormonal factors play an important role in this disease. How steroid hormones influence the disease pathophysiology is the current area of research. Following are the proposed hormonal influences shown in Table 2.

Progestosterone or progestin commonly available like the oral, depot preparations and the LNG-IUD have been used. These were used as progestosterone has many actions which are anti-estrogenic. But none of these showed consistent response. On the contrary these were shown to influence the growth adversely leading to the understanding of the existence of PRs in myoma cells. Biochemical studies suggest that progestosterone, progestins modulate myoma mitotic activity.

Likewise came the understanding necessitating specific hormonal receptor modulators. Selective estrogen receptor modulators (SERMs), like Tamoxifen, Raloxifene, seemed promising by repressing growth, reducing proliferation, and there was also a tumor reduction by 50%. But this lasted temporarily. The reason for this was found to be absence of apoptosis. The method of growth inhibition in response to estrogen deprivation is as shown in Table 3.

Thus, the data on in vitro study suggests that creation of a hypoestrogenic milieu within leiomyomas reduces tumor volume independent of apoptosis and therefore is less effective. It is well understood that leiomyomata are unicellular in origin with identical glucose-6-phosphatase-dehydrogenase electrophoretic type cells arising from a single neoplastic smooth muscle cell. Cytogenetic studies have revealed consistent abnormalities including translocations and deletions involving several chromosomes but most commonly the chromosome 12. These mutations could be the cause of absence of apoptosis.4

Selective progesteron receptor modulators (SPRMs) represent a new class of PR ligands. These are also known as “mesoprostogens”. SPRMs exert clinically relevant tissue selective progesterone agonist, antagonist or mixed agonist/antagonist effects on various progesterone target tissues. Asoprisnil (J867) is the first SPRM to reach an advanced stage of clinical development for the treatment of symptomatic uterine fibroids and endometriosis.

Thus wide choice of drugs has now become available to treat myomas. They can be undertaken as part of expectant management, for alleviation of symptoms, to reduce the size as adjuvant to surgery and sometimes as an alternative to surgery (Table 1). Prior to medical management, one must be sure of the diagnosis.

The aims of medical management are as follows:
• Expectant management with alleviation of symptoms
• Improve the hemoglobin status and menorrhagia before surgery
• Minimize the size and vascularity before surgery to facilitate surgery
• To facilitate hysteroscopic or laparoscopic surgery
• Alternative to surgery in perimenopausal women with high risk factors
• Postponement of surgery.

### Drugs for Medical Management

#### Oral Contraceptives

High dose estrogens contribute to the growth of fibroids. Low estrogen containing pills like the low dose pills decrease the size of fibroids and reduce the endometrial thickness. Thus combined pills can be used to treat small fibroids causing menorrhagia. This could be attributed to subphysiologic concentrations of estrogen.5 Low dose cyclic or continuous estrogen and progesterone pills can be used after GnRH-Ag therapy as “add-back” but such usage is still investigational.

### Progestogens

Useful in an ovular menorrhagia and achieve reduction in size of fibroids.

*Norethindrone acetate* in the dose of 5–10 mg daily from day 5 to day 20 of the cycle can be used.

*Injection DMPA*: *Depot medroxyprogesterone acetate*—After 6 months use: effects.

• 30% Amenorrheic
• 70% Improvement
• 15% Had increase in Hb levels
• 48-33% Reduction in mean uterine volume

*LNG-IUD (Mirena)*: It is an alternative route of using progesterone. It is a prostagastert with 52 mg Levonorgestrel which acts directly on the endometrium. The endometrium becomes thin and inactive. There is a reduction in the size of small fibroids. After 3 months of usage, the average blood loss is 85% less and after 12 months it is 97% less.6 It has been licensed for 5 years usage. Although there are no randomized trials of LNG-IUS in women with fibroids this option could be considered for women with heavy uterine bleeding caused
predominantly by intramural fibroids and who are poor surgical candidates.

**Fibroplant:** It is a progestasert similar to Mirena but is unique as it is frameless. It releases levonorgestrel at the rate of 14 μg/day. Its frameless nature increases its compliance. It is associated with a low incidence of amenorrhea and thus is one step ahead of framed progestasert. More trials are required for its usage in fibroids.

Progesterone is known to cause leiomyoma cell proliferation and growth in vitro and in vivo.⁷ MPA blocked the fibroid shrinking effect induced by GnRH agonist.⁸ Thus progesterone has self-contradicting clinical results. The reason that progestogen containing therapies achieved symptomatic relief as seen in the past was more due to correction of hormonal imbalance or reduced vascularity.

**Androgens**

**Danazol:** Isoxazole of 17 b-ethyl testosterone exerts androgenic action by suppressing sex hormone binding globulin. It is given in the dosage of 100–200 mg daily for 3–6 months. Several studies have shown that Danazol reduces the size of fibroids by 20–25%. Danazol inhibits aromatase in leiomyomata⁹ and may promote fibroid regression.¹⁰ It has androgenic as well as hypoestrogenic side effects and therefore is not popularly recommended.

**Gestrinone:** It is a trienic steroid with both anti-estrogenic and anti-progestogenic properties. Large doses are required to reduce the size of fibroids. There is a Brazilian study which included 24 patients with large fibroids. It was observed that all patients had menstrual suppression and the uterine volume reduced from 724.9 cm³ to 450.73 cm³ in 6 months. This effect was achieved within 2 months and lasted up to a year after treatment.¹¹ Minor androgenic side effects were seen with a mean weight gain of 3.4 kg in 6 months. No menopausal symptoms were seen. Not popularly used due to severe androgenic side effects especially water retention.

**Antifibrinolytics**

Tranexamic acid is a synthetic derivative of amino acid lysine. In the dose of 2–4 gm/day given in divided doses, it reduces blood loss associated with fibroids significantly. It has no effect on blood coagulation. As per the Cochrane review antifibrinolytics therapy causes a greater reduction in objective measurements of heavy menstrual bleeding.

**GnRH Agonist**

Goserelin, Leuprorelin, Buserelin are commonly used drugs. Agonist creates a pseudo menopause like state, thus reduces the size of fibroids by about 12.5 mL on an average. It reduces intraoperative blood loss and is efficacious in women awaiting in vitro fertilization (IVF) cycles or nearing menopause with uterine fibroids.

Following benefits were observed: Improved hemoglobin concentration, relief of pressure symptoms and reduction in the vascularity of the tumor leading to reduced blood loss at myomectomy. It also reduces the size of the fibroids.¹²

**GnRH Antagonists**

Cetrorelix and Ganirelix are the most common used antagonists. They cause immediate suppression of pituitary. The basic advantage is reduction in treatment time and faster restoration of ovarian activity. GnRH antagonistic therapy has certain drawbacks like:

- Excessive fibrosis makes capsule identification difficult
- Incomplete removal of fibroid
- High recurrence rate in treated (65%) as compared to untreated (28%) women
- Prolonged pituitary suppression
- Prompt increase in the size of fibroids after discontinuation
- Adverse hypoestrogenic effects
- Not cost effective.

**Mifepristone**

Mifepristone or RU486 is an anti-progestogen drug which blocks the effect of progesterone at the receptor level. It reduces the size of fibroids and is as effective as a GnRH analog when used for 3 months. It is cost effective, has fewer side effects and greater patient acceptability. In a non-randomized study, a daily dose of 10 mg RU486 reduced the volume of myomas by 40% in 3 months with minimal side effects and with no effects on bone mineral density.¹³ A trial comparing GnRH agonist and 12.5 mg RU486 revealed 20% reduction in the myoma volume, but the GnRH group had a higher recurrence rate after cessation of therapy.¹⁴

**Newer Drugs**

**Growth factors** This plays a relevant role in the pathophysiology of fibroids by inhibiting growth through its effect on the myometrium. This would be the basis of future therapy.

**SERMS:** Low estrogenic states are associated with regression of myoma size. The treatment of premenopausal women with an estrogen receptor (ER) antagonist, however, has produced disappointing results. Fulvestrant is a pure ER antagonist that binds to and promotes dramatic ER down regulation. A prospective randomized controlled trial found no inhibition of fibroid growth when comparing fulvestrant with placebo in premenopausal women with uterine fibroids requiring hysterectomy.¹⁵Raloxifene has shown reduction in the size of fibroids in postmenopausal women but in another randomized controlled trial it has shown no effect on myoma size or menstrual pattern after 6 months of treatment in premenopausal women.¹⁶

**SPRMs:** New class of PR ligands. The PR exists in two isoforms: (1) PR-A and (2) PR-B. PR-A decreases estradiol responsive-
Aromatase inhibitors: It is observed that aromatase, the enzyme that converts testosterone (T) to estradiol (E2) and androstenedione (A) to estrone (E1), is expressed in higher levels in myoma tissue than myometrium. Inhibition of aromatase could potentially reduce myoma size.

Fadrozole: It is an aromatase inhibitor tried in the dose of 2 mg daily and reduced myoma volume by 71% in a perimenopausal woman after 2 months of treatment. But this is a case report and more study is needed.

Pifenidone: This is an agent that inhibits DNA synthesis, cell proliferation, and collagen synthesis in both normal myometrial and leiomyomas smooth muscle cells, probably through inhibitory effects on growth factors implicated in fibroid growth. It is used as an antifibrotic in patients with pulmonary fibrosis and has shown reasonable safety. It can be an effective non-steroidal treatment for fibroids as it inhibits myometrial and fibroid cell proliferation. It is currently under trial.

Surgical Management of Myomas

The most common symptoms for which treatment is sought:

- Excessive uterine bleeding
- Pelvic pressure and pain
- RPL
- Occasionally infertility.

Indications for surgical management of uterine myomas: American College of Obstetricians and Gynecologists (ACOG) and American Society for Reproductive Medicine (ASRM).

- Abnormal uterine bleeding not responding to conservative treatments.
- High level of suspicion of malignancy.
- Growth after menopause.
- Infertility with distortion of the endometrial cavity or tubal occlusion.
- Pain or pressure that interferes with quality of life.
- Urinary tract frequency or obstruction.
- Iron deficiency anemia related to abnormal uterine bleeding.

Myomectomy

Myomectomy for removal of intramural and subserosal myomas solely to improve or to treat infertility has been controversial. The potential risks and consequences like postoperative adhesions that may reduce fertility and the need for cesarean delivery are real. The data from studies of IVF outcomes in women with or without myomas certainly suggest that historical skepticism regarding the value of myomectomy in infertile women is justified. Results of two myomectomy series also challenge the therapeutic value of myomectomy in otherwise asymptomatic infertile women with intramural and subserosal myomas. In both studies it was observed that cumulative results of over the first two postoperative years related primarily to duration of infertility and presence or absence of other infertility factors but not to the size or site of the large myoma removal.

There are recent studies though which have evaluated the reproductive outcome before and after laparoscopic or abdominal myomectomy for submucous or intramural myomas. Campro et al. studied 41 out of 128 patients who underwent myomectomy as only these matched the criteria of the study designed. They concluded that myomectomy significantly improved pregnancy outcome in patients with subserous or intramural fibroids probably removing a plausible cause of altered uterine contractility or blood supply. The main determinants of pregnancy rate after surgery are patient age, diameter and intramural localization of the myomas and type of surgery.

Keeping these controversies in mind there are guidelines designed for myomectomy by the ACOG (Table 4).

Myomectomy by any route is still a controversial subject. According to the available evidence based on a comprehensive review slightly less than two-thirds of the women with uterine leiomyomas and otherwise unexplained infertility conceived after myomectomy. There is a renewed interest in the procedure due to postponement of pregnancy until later age thus myomas getting a chance to thrive. Also with the advent of minimal access surgery and better imaging modalities choice of route requires to be addressed. Comparison between laparoscopic and abdominal myomectomy is shown in Table 5.

</tr>
<tr>
<td></td>
<td>Minilaparotomy incision can be used and maneuvering achieved by use of uterine manipulators</td>
<td>• Removal of myoma can be through a small incision and the uterine suturing too can be done through this incision either in the abdominal wall or vagina</td>
</tr>
</tbody>
</table>
There are various factors which influence the choice of route of myomectomy:
- Size, number and site
- Expertise of the surgeon
- Control of hemorrhage
- Suturing technique and the resultant scar integrity
- Available facilities.

Contraindications for laparoscopic myomectomy:
- Medical conditions likely to be worsened with abdominal distension and Trendelenburg position for a long period
- Diffuse leiomyomas
- More than three myomas equal to or more than 5 cm
- Uterine size more than 16 weeks of gestation
- Myoma more than 15 cm in diameter
- Incision totaling to more than 15 cm.

There are quite a few authorities now not strictly adhering to these criteria and no clear-cut offs exist to determine the approach. The decision is situational.

The two most important prerequisites before a myomectomy requiring consideration are:
- Preoperative treatment with GnRH analogs
  A Cochrane Review suggests that the use of GnRH analogs for 3–4 months prior to surgery reduces both uterine volume and fibroid size. They are of benefit in reducing iron deficiency anemia if present and also help in reducing the intraoperative bloodloss. Reduction in size facilitates the procedure to be completed by laparoscope. The disadvantage is the extensive dense fibrosis which may occasionally develop. Also in our experience it does not help much in those fibroids which have already undergone cystic degeneration.
- Clear and informed consent
  Clear discussion and the choice of route should be discussed with the patient. The risk of vascular and visceral injury should be discussed. Also sometimes the necessity of hysterectomy should be discussed. Some authors have quoted the risk of hysterectomy to be as high as 1 in 100.

For subserous myomas laparoscopy can offer a minimal invasive alternative to laparotomy (Figs 2A to E). It is associated with faster postoperative recovery and potentially less postoperative adhesions (Fig. 3). Main concern remains with respect to removal of the myoma after it has been removed either by ligation or use of energy. But it is definitely satisfying to use laparoscopic access in these fibroids. Asymptomatic subserosal fibroids do not always necessitate surgery. Myomectomy for intramural fibroid is an issue requiring appropriate modality of treatment. Laparoscopy has certain important advantages especially with respect to adhesions. At the time of second look laparoscopy, adhesions were found less frequently and were less extensive in patients who had laparoscopic myomectomy. The critical risk factors were found to be the posterior location of the myoma and the number of incisions.

Recent evidence favors safety and reliability of laparoscopic approach. Prospective randomized controlled trials comparing laparoscopic myomectomy with laparotomy myomectomy will clarify the status further. Bullett and coworkers compared postoperative adhesions after laparoscopic versus laparotomy myomectomy in a prospective controlled trial and found it to be advantageous.

**Advantages of Laparoscopic Myomectomy**
- Shorter hospitalization
- Faster postoperative recovery
- Reduced postoperative pain
- Reduced ileus and thromboembolic phenomenon.

**Limitations of Laparoscopic Myomectomy**
- Deep intramural fibroids may not be localized due to lack of tactile sensation; intraoperative transvaginal sonography could be undertaken for the same.
- **Skills of the surgeon**: Experience and sound suturing skills are essential.
- Number of instruments and various angles of insertion to approach the surgical site are limited, posing technical difficulties.
- Removal of myoma from the abdominal cavity may be difficult.
- Accurate edge apposition may be difficult.
- Operating time.
As for submucosal fibroid (Figs 4A and B) hysteroscopy approach is the current gold standard. Currently the main indications for hysteroscopic myomectomy (Table 6) in infertile patients or in candidates for HRT are the presence of abnormal uterine bleeding and submucous myomas, including asymptomatic cases.

Grading of these myomas is essential to better plan the surgery. Based on dimensions and site, the European Society of Hysteroscopy has proposed the classification shown in Table 7.

G0 can be handled by an inexperienced surgeon. G2 requires considerable skills. This classification however does not mention the dimension of the fibroid. The operability depends on the intramural component of the tumor. The thickness of the peritoneum remaining between the inner deep margin of the tumor and the serous peritoneum of the uterus is important. The safety margin set by most is at 0.5–1 cm. Also the angle proposed by Donez et al. proves less accurate as it does depend on the dimensions of the myoma.

There is therefore one more classification proposed to evaluate the viability of hysteroscopic surgical treatment.\(^{29}\)

The new classification (NC) is based on the subjective analysis of parameters that make surgery more difficult. The four criteria, as discussed in Table 8, were considered.
Table 6: Indications for hysteroscopic myomectomy
- Abnormal uterine bleeding
- Infertility (including asymptomatic cases)
- Candidates for HRT (including asymptomatic cases)

Accordingly the myomas are scored and classified as in Table 9. The scoring of the myomas is done and then the treatment is suggested as follows (Table 10).

Both these studies require to be compared on a larger patient group. They can actually complement each other.
Myomectomy at C-Section

Traditional teaching has always been to remove only subserous or pedunculated myomas at the time of C-section. Torrential hemorrhage and infection later on were the prime concerns with intramural fibroids. There is renewed interest in the recent past with the advent of superior surgical techniques and better antibiotics. Intramural fibroids have been successfully removed at the time of cesarean section. We have attempted ligation of the uterine artery at the time of C-Section a keen to uterine artery embolization (UAE). Our observation has revealed increased febrile morbidity in these patients. We require to statistically evaluate our data.

Alternative Surgical Treatment: Myolysis

Electrical, thermal and ultrasound energy sources have been used to coagulate and devascularize symptomatic fibroids. Most such techniques involve laparoscopy directed placement of energy probes. LASER has been used giving rise to dense adhesions. Bipolar energy so far has given better results. Magnetic resonance guided focused ultrasound surgery of uterine fibroids (MRgFUS) is one such modality but without laparoscope. None of these myolysis approaches have established safety in women desiring fertility.

Magnetic Resonance Guided Focused Ultrasound Surgery of Uterine Fibroids

It is a noninvasive, outpatient procedure which uses high doses of focused ultrasound waves to destroy uterine fibroids without affecting any of the other tissues around the fibroid. MRI mapping of the fibroids is done prior to the procedure. The focused ultrasound energy is directed to a small volume of the fibroid raising its temperature high enough to cause thermal ablation without impacting other tissues. Pulses of energy are repeated until the entire volume is treated.

This method suffers from lack of sufficient evidence with respect to volume of the studies, follow-up, comparisons with other modalities, etc. It is proposed that 50% of the fibroid tissue is destroyed which still require to be quantified. Also one wonders whether such partial destruction of fibroid is beneficial to alter the pathogenesis of the disease. This treatment cannot be used for fertility preservation or enhancement.

Use of adjuvant therapy with the GnRH agonists potentiates the thermal effects of MRgFUS in women undergoing treatment of uterine fibroids. Transvaginal probe guided sonications have been tried, and hysterectomy specimens have revealed no serosal heating or burning and hold some promise and are currently under evaluation.

Table 11: Complications of UAE

- Related to angiography: DVT, pulmonary embolism
- Amenorrhea
- Premature ovarian failure
- Perforation
- Infection
- Tissue necrosis

Uterine Artery Embolization

Uterine artery embolization has been used in the treatment of postpartum hemorrhage (PPH) since the 1970s, but is relatively a new option for the treatment of fibroids. It entails angiographically guided occlusion of the uterine artery with pellets, which decreases the size of the fibroids. Complications can arise as discussed in Table 11.

The fertility rate after this procedure when performed for PPH were not adversely affected. The risks associated with this procedure included hysterectomy, premature ovarian failure and infertility from radiation exposure following UAE as per the earliest studies that evaluated the fertility potential and labor performance of women. It concluded that the risks associated with UAE compared favorably with those associated with myomectomy. There are multiple case reports of successful pregnancy outcomes after UAE. However, numerous complications also have been reported. A review of 50 such published cases after UAE reported the following complications:

- Malpresentation (17%)
- SGA (7%)
- Cesarean section (56%)
- Premature delivery (28%)
- PPH (13%).

Safety of UAE with respect to fertility conservation is still controversial. An ACOG Committee opinion from 2004 states: “there is insufficient evidence to ensure its (UAE) safety in women desiring to retain their fertility, and pregnancy-related outcomes remain unstudied. The ACOG considers this procedure investigational or relatively contraindicated in women wishing to retain fertility...” Myomectomy remains the standard of care in patients who wish to retain fertility. UAE’s effect on fertility and pregnancy needs to be studied further. Meanwhile this technique should be used only in those patients desiring to retain fertility without any other feasible option.

Hysterectomy

The definitive treatment for uterine myoma is hysterectomy though at the cost of functionality. Hysterectomy as a modality can be chosen only when fertility is not desired by the patient. The risk of mortality associated with hysterectomy is
Table 12: ACOG criteria for hysterectomy for leiomyomas

- Asymptomatic myoma which are abdominally palpable
- Excessive uterine bleeding leading to flooding, clots or frequent and long lasting or leading to anemia
- Myomas causing pelvic discomfort

approximately 1/1,000 procedures. Mere presence of a fibroid does not warrant a hysterectomy. Also hysterectomy in the case of myoma requires considerable surgical expertise. Proper patient selection is mandatory and unindicated intervention should be avoided. The ACOG Committee has developed certain criteria (Table 12) for hysterectomy in leiomyomata of uterus.

The guidelines also mention certain important preoperative prerequisites such as:
- Confirm the absence of cervical malignancy
- Eliminate an ovulation and other causes of abnormal bleeding
- Confirm the absence of endometrial malignancy in the presence of abnormal bleeding
- Surgical risk assessment due to anemia and treat it if necessary
- To consider patient’s medical and psychological risks concerning hysterectomy.

Management Guidelines

Management of the uterine myomas must be individualized. The factors to be considered are:
- Symptoms
- Size
- Fertility status
- Rate of growth.

Asymptomatic Patients

In these patients, we would like to give prime importance to expectant management, as this is the one, which is easily forgotten. Lately there is increasing tendency to remove every fibroid seen on the uterus just because it can be done easily especially with newer modalities. However, we must remind ourselves that fibroids are a very occurrence. More than 50% of women would have one or two fibroids by the time of menopause and many of them are entirely asymptomatic.

In our series of 216 cases of fibromyomas, 180 were in premenopausal group, and we encouraged expectant management with medical and surgical management when required. It was observed that among the asymptomatic cases even with large (more than 6 cm) tumors, 39% did not require surgery. Among symptomatic and large tumors, 28.5% could be managed non surgically, while among asymptomatic and small (less than 6 cm) tumors, 63.3% did not require surgery. Patients without symptoms with uterine enlargement less than or equal to 12 weeks gestational size and slow uterine growth (< 6 weeks size in 1 year) should be managed expectantly regardless of fertility status.

Patients desiring pregnancy can be counseled that myomas rarely impair fertility or complicate pregnancy. Asymptomatic women with myoma greater than 12 weeks gestational size who desire pregnancy should attempt conception. Myomectomy may be considered for women who fail to conceive after unprotected cohabitation or who have repeated pregnancy losses if a thorough workup for infertility or RPL is negative.

Currently no data supports routine performance of myomectomy for arbitrary sized myoma in asymptomatic women desiring fertility and therefore these can be managed expectantly.

Traditionally, large asymptomatic fibroids in women not desiring pregnancy have been managed by hysterectomy. This decision is based on the following rationale:
- Large myomas interfere in the clinical evaluation of adnexa which could delay the detection of ovarian malignancy
- It would help in early detection of sarcomas
No data supports this rationale
Any treatment offered to asymptomatic patient should be evaluated and be of clearcut benefit with minimum risks.

Symptomatic Patients

It is essential to establish that the symptoms are attributed to the myoma. Many a times myomas are an incidental finding not necessitating intervention. Myomectomy may be offered to women desirous of fertility but proper criteria should be adhered to before undertaking any definitive treatment modality.

In conclusion, there are a plethora of treatment modalities available for treating leiomyomas. It is important that each clinician keep himself updated with these advanced data to better treat our patients. One should keep an open mind to different aspects of therapy, base diagnosis on sound clinical judgment and offer treatment based on evidence based data. Proper patient selection and individual tailor made treatment should be the aim.

REFERENCES

5. ACOG educational and technical bulletin, p. 869.
Genital prolapse is at least as old as Egyptian mummy.

Prolapse simply means downward descent. While from the angle of a physicist its root cause would be incessant pull of gravity; from the viewpoint of a gynecologist it would be failure of normal structural, functional and positional antigravity mechanism and/or operation of some progravity force (e.g., any chronic downward force) from above on the organs in question. Anyway, before getting down into the pathological anatomy and surgical anatomy of prolapse (as the chapter heading demands) a review of the other types of pelvic anatomy is essential because these are all inseparably interrelated (Fig. 1).

CONCEPTUAL TYPES OF FEMALE PELVIC ANATOMY

- Structural anatomy
- Positional anatomy
- Functional anatomy
- Pathological anatomy
- Surgical anatomy.

STRUCTURAL ANATOMY

This means the structures—“as is and where is” undisturbed by any pathological process or force. Since to any postgraduate (to whom this book is directed) this kind of descriptive anatomy is expected to be all too known this will not be detailed here exhaustively except through drawings for the purpose of comparison with pathological anatomy (Fig. 2).

However, one misconception that many gynecologists tend to suffer in connection with prolapse is that—they subconsciously take the structural anatomy as it is found in a young nulliparous woman only “as normal” and any deviation from it makes their perfectionist mind somewhat unhappy—
Prolapse: Pathological Anatomy and its Bearing to the Selection of its Treatment

whereas, in real life, even normal structural anatomy varies with parity and age.

**POSITIONAL ANATOMY**

Since prolapse is a matter of position (i.e. downward descent from normal position) review of some important facts about the positional anatomy of the organs concerned is necessary—not only to label a case as one of prolapse but also to allocate degree to it. Besides, it is also necessary in order to precisely plan the repair.

**Positional Anatomy of Uterus**

In adult woman in erect posture, except in approximately 15%, uterus lies in a forwardly bent attitude, i.e. in anteverted and anteflexed state. It is noteworthy that of this natural state, it is specially the feature of anteversion which acts as an inherent mechanism against occurrence of prolapse even under great downward stress. This is because in an anteverted position the axis of the cervix meets the axis of vagina at approximately 90° angle and so, when a woman is standing, the cavity of the uterus is more horizontal than vertical (Fig. 3) and hence it never comes under vertical downward stress. Besides, the above fact also implies that, for uterine prolapse to occur, the axes of the above two organs has to come more or less in the same line by some mechanism.

Secondly, in a standing woman, the internal os is found to lie approximately in level with the upper border of symphysis pubis and the external os at about the level of ischial spines. Hence, logically, any descent of uterus from the levels mentioned above should be labeled as a case of prolapsed uterus.

**Positional Anatomy of Vagina**

*Not a vertical canal:* Normally, vaginal canal extends obliquely upward and backward from the vulva at an angle of 60–70° to the horizontal or in other words, it is not a vertical canal. Hence, any rise in intra-abdominal pressure has the closing effect on vaginal canal by causing apposition of anterior and posterior vaginal wall.

*Not a straight canal:* In connection with prolapse another important positional feature of vagina to appreciate is—that its canal is not straight. It is actually angulated backward at about halfway of its length (called vagino-pelvic angle—Fig. 4), which means that upper half of the vagina is more or less horizontally placed. This is again another mechanism by which vagina not only escapes the vertically downward stress but under stress its upper half tends to close.

*Not a canal at all:* The third point to note in this context is, specially the lower part of the vagina is H-shaped in cross-section which means that its anterior and posterior walls normally lie in apposition thereby obliterating its canal (Fig. 5). Vaginal canal assumes this configuration because it is fixed (suspended) laterally by the lowermost part of Mackenrodt’s ligaments.

Obviously, for prolapse to occur whether uterine or vaginal or both, nature’s above well-engineered positional anatomy has got to be disturbed first.

**FUNCTIONAL ANATOMY**

While this is the ace matter both from physiological and therapeutic (surgical and nonsurgical) angle, besides its far reaching psychological, social and sexual implications, it is not yet fully understood because of the following reasons:

- The correlation between somatic and autonomic neuromuscular activity of pelvic floor muscles cannot yet be fully explained.
- Agonist and antagonist activity of pelvic floor musculature do not satisfactorily explain the functional anatomy.

---

*Fig. 2: Structural anatomy of female reproductive tract*

*Fig. 3: Normally, the axis of cervix and that of vaginal canal cut each other almost at right angles, which is an inherent positional mechanism for prevention of prolapse*
may be noted that the altered anatomy should only be taken as pathological if it makes “the patient” unhappy (not the gynecologists), e.g. if she has seen or even felt something at her introitus and/or has noticed some undesirable alteration of some function of that region, e.g. that of micturition, defecation, coitus, etc. then only the anatomy may be called as pathological.

**Purpose**

A precise knowledge of pathological anatomy is absolutely essential to plan appropriate treatment, i.e. whether the patient requires nonsurgical or surgical treatment, and, if surgery—what surgery and to what extent it should be carried out.

**Assessment**

For assessing the precise pathological anatomy in a case, besides clinical examination in unstressed and also stressed condition (e.g. asking the patient to strain in lying and if necessary, sitting, squatting or even standing position) investigations like ultrasound, both abdominal and transperineal, intravenous urography specially for determining the position of ureters, back pressure changes, etc. urodynamic studies, even MRI—to assess the extent of muscular and fascial damage may be employed in suitable cases. Of course, per rectal examination is a must specially to differentiate rectoceles from enterocele.

**ORGANWISE DESCRIPTION**

**Pathological Anatomy of Anterior Vaginal Wall Prolapse**

Prolapse of anterior vaginal wall most commonly presents as cystocele (Fig. 6). However, rarely, through its lowermost part—the posterior wall of urethra may bulge, when it is called urethrocele. Disruption or degeneration of the layer of normal fascial condensation around the vaginal canal is the cause of such prolapse and to prevent recurrence after repair this fascial tissue has to be repaired.

**Pathological Anatomy of Posterior Vaginal Wall Prolapse**

**Upper Third Prolapse**

This includes enterocele of various degrees and post-hysterectomy vaginal vault prolapse (Fig. 7).

These two conditions constitute true pelvic hernia because these have peritoneum lined sac and hence the basic principles of hernia repair apply, i.e. dissection of the hernial sac, closure of the neck of the sac and building
local support (usually by plication of what is felt of the uterosacral ligament) to prevent recurrence. In the cases of vault prolapse, where necessary, support may be sought from the anterior longitudinal ligament that lies on the anterior surface of sacrum through a sling of Decron or Mersilene tape—a procedure which must be done through laparotomy. Recently, however, transvaginal colpopexy with sacrospinous ligaments of both sides is being preferred for the purpose—this being much simpler and easier.

As a preventive step to this form of herniation some gynecologist routinely plicate the uterosacral ligaments in the midline by a few stitches.

**Middle Third Prolapse**

This presents as rectocele. Colpoperineorrhaphy up to 1.5 cm beyond the limit of the bulge of rectocele with plication of rectovaginal fascia and tightening of levator ani (puborectalis) is the commonly practiced approach to tackle this. Recently, a new approach about repair of rectocele. Recently, for cases of isolated rectocele without significant perineal or levator laxity, the author has been doing “site specific repair” which means circumscribed repair of the weak and sacculated area only. This avoids performance of routine perineorrhaphy which is known to have many side effects (see below). None of the six cases done over last ten years have come back with recurrence.

**Lower Third Prolapse**

This includes cases of lax introitus, wide open introitus and lax perineum. All these patients have underlying perineal tissue tear. These patients usually complain of unsatisfactory intercourse, excess exposure and local vulvovaginal dryness. They need just good perineorrhaphy with buttressing of levator ani.

**The Debate about “Routine” Perineorrhaphy**

A concept prevailed for many years that no operation for prolapse is complete unless one has done perineorrhaphy with it—be it repair of cystocele, be it a case of simple uterine prolapse or any other kind of prolapse. This myth has been dispelled by Jeffcoate. He found this procedure is required only in 50% operations for prolapse. The practice of routine perineorrhaphy was based on the postulate that uterus is supported by vagina and the vagina (both its anterior and posterior wall) is supported by the perineum, which have been found to be unproven (see under supports of vagina later).

The advantages of avoiding perineorrhaphy (where it is not specifically required) are as follows:

- Patients are remarkably free from local postoperative pain and discomfort
- Occurrence of postoperative retention of urine and consequent cystitis are quite rare
- The chance of occurrence of anatomical dyspareunia later due to narrowing of introitus and lower vagina and also that from painful and/or hypersensitive perineal scar is virtually eliminated.

**An Important Note about Site-Specific Repair**

The proponents of this type of repair believe that pathologically there are two types of vaginal prolapse as follows:

1. Distension prolapse
2. Displacement prolapse.
**Distension Prolapse**

This occurs due to attenuation of vaginal wall ‘only’ without any loss of its fascial attachments. So, here the vaginal rugae will be lost and vaginal wall will look smooth.

**Displacement Prolapse**

This results from loss of attachment of lateral vaginal walls from the pelvic side walls and hence here vaginal rugae will be intact.

**Local Vaginal Pathology Consequent to Prolapse**

In long-standing vaginal prolapse, vaginal walls get keratinized due to constant exposure and friction; some also develop pigmentation, even decubitus ulcer. In postmenopausal women, signs of vaginal atrophy are present and these patients get benefited by preoperative topical estrogen therapy.

**Pathological Anatomy of Uterine Prolapse**

The three degrees of descent of uterus from its normal position has been depicted in Figure 8. Uterine prolapse can occur on its own due to weakness of direct supports of uterus, i.e. that of Mackenrodt’s and uterosacral ligaments in which case cystocele and rectocele may not be associated. However, in the same case if there has also occurred disruption of vesicovaginal or rectovaginal fascia, cystocele and rectocele are also present.

Primary prolapse of uterus is almost always associated with some degrees of elongation of supravaginal cervix due to chronic pull of cardinal ligaments on it to check the descent and also due to interference with venous and lymphatic drainage from this part. If the supravaginal elongation is much, though cervix may be seen outside the introitus, the actual uterus may still be positioned up in the pelvis.

**SURGICAL ANATOMY**

This means pathological anatomy with surgical plan superimposed in it. This entails, on the part of the surgeon, to find out the exact pathological anatomy so as to be able to plan the technique and extent of surgery keeping in mind that he/she has not only to put the structural anatomy right but also to ensure restoration of previous functions or at least the functions desired by the patient as required for meeting her social, psychological and biological situation.

Besides this, particularly for prolapse repair operation, a gynecologist must also have a clear concept about the various supports of the female reproductive tract (see later). To this end he/she also needs to do purposeful local examination in order to assess what supporting structures are presently available for use to repair and reconstruct. In this context a precise knowledge about the bones of the pelvis particularly the ligaments in and around the pelvic girdle is also essential because in some cases these may have to be utilized to organize support of the prolapsed organs. For example:

- pubic bones in the context of repair of stress incontinence
- sacrospinous ligaments (Fig. 9) for support of the posterior vaginal wall prolapse and vault prolapse (Fig. 9)
- anterior longitudinal ligament of sacrum for vault prolapse, etc.

In addition to above, the gynecologist also has to carefully assess the structural and functional state of the viscera intimately related to the prolapsed reproductive organs (Fig. 10) like that of the bladder, of the ureters, the urethra, the rectum, the anal canal and even that of the peritoneal recesses like POD. The purpose of this are twofold:

1. Ensuring their rehabilitation
2. To be able to take adequate care to avoid injury to these during the course of repair.

---

**Fig. 8:** Stages of uterine prolapse

**Fig. 9:** Sacrospinous ligament
A Brief Note on Neuromuscular Anatomy in Relation to Surgical Treatment of Prolapse

- It is nearly impossible to restore neuromuscular function or lost reflex activities by restoring the anatomy surgically.
- *The vulnerability of “Levator ani nerve”: This nerve arises from the sacral roots and courses on the superior surface of the coccygeus muscle where it lies approximately 3 cm medial to the ischial spines. This important nerve is vulnerable to surgical injury during the following two operations for prolapse:
  - Sacrospinous ligament fixation and
  - Paravaginal defect repair.
  If this happens, this may result in chronic pelvic pain and/or dysfunction due to atrophy of this rather large vital muscle.
- The possible reason why some women develop ‘just’ pelvic organ prolapse and others develop urinary or fecal incontinence—different innervation of the levator ani and that of the striated urethral and anal sphincter.

Supports of Female Reproductive Tract and Their Relation with Pathological Anatomy of Prolapse

Most undergraduate books give neat structural classification of supports of uterus as upper group (round ligament and broad ligament), middle group (Mackenrodt’s ligament and uterosacral ligament) and lower group (pelvic diaphragm and urogenital diaphragm) which is helpful, but for postgraduate level one has to understand the supporting mechanism from the functional angle and also to critically assess the reality about the checking role of the various supporting structures in the occurrence of prolapse. From this point of view supports of uterus can be classified as:
- Static group of supports
- Dynamic group of supports.

Static Group of Supports

This means support by nonmobile, nonstretchable (hence susceptible to breakage under extreme stress) static structures, and ligamentous support constitute this category. These structures, which are generally very strong, hold the organs in their right place at all time, i.e. in both stressed and unstressed condition. The examples of these are—Mackenrodt’s ligament, uterosacral ligament and pubocervical ligaments (Fig. 11). In fact, this group constitutes the most important and the only real direct support for the uterus. Structurally, these are condensation of pelvic cellular tissue with some plain muscle fibers in them. Given below is a brief description of these ligaments.

*Mackenrodt’s Ligament (Transverse Cervical Ligament)*

Medially it is attached to supravaginal cervix and vault of vagina and laterally to a wide area in lateral pelvic wall (Figs 11 and 12). It lies in the space between the broad ligament above and aponeurosis on the pelvic floor muscles namely those on levator ani and obturator internus below. This is the thickest and the strongest support of the uterus.

*Uterosacral Ligament*

It stretches from the supravaginal cervix and posterior vault—to the front of the sacrum encircling the rectum (Fig. 13). This ligament is, in fact, the thick posterior margin of the Mackenrodt’s ligament. Under downward stress, due to the above attachment of the ligament, the vaginopelvic angle...
of vagina, become more acute which has occlusive action on vaginal canal. Besides, in standing position, the cervico-isthmic attachment of this ligament keeps the projection of the cervix oriented toward the central tendinous point of perineum, which, through dynamic support mechanism, works as complementary antigravity back up.

**Pubocervical Ligament**

Normally, this is not a well-defined ligament but usually become discernible in the presence of cystocele and anterior vaginal wall prolapse.

**Controversy about Vaginal Fascia**

There are two large reviews which have challenged the existence of structures like—pubovaginal fascia, bladder-pillar, pubovesical fascia, mesovaginal fascia, uterovesical ligament, musculofascial hammock, etc.  

**Dynamic Group of Supports**

A complex muscular apparatus that is formed by the muscles of pelvic diaphragm and the urogenital diaphragm constitute the dynamic support system (Figs 14 to 16). The system is mediated by a ‘tonic’ and ‘phasic’ reflex activity through type I (fast twitch) and type II (slow twitch) muscle fibers integrated at central nervous system. This comes into play for every effort involving Valsalva maneuver like defecation, lifting, running and other forms of sports activity and also for every incidence of increased intra-abdominal pressure like coughing, laughing, sneezing, etc. It has been found that any situation where the intra-abdominal pressure exceeds 100 cm of water it strains the pelvic supporting mechanism. Besides above, pelvic muscles also directly take the weight of the uterus, vagina, etc.
Of the above apparatus, which acts in a concerted manner, it is particularly the reflex contraction of puborectalis part of levator ani which plays the most important role in the following ways:

- Causes elevation of the central tendinous point of the perineum (to which it is inserted) which in turn effects the following—occlusion of the vagina, alteration of vaginopelvic angle which offsets the directional effect of stress, works as a supporting cushion for the vagina
- By directly opposing the expulsive forces
- By protecting the relatively stiff and therefore fragile static group of supports (see above) from overstretching and disruption.

Central tendinous point of perineum, being such a strategic supporting structure of female reproductive tract, its various attachments need a review. Attached to this are the following—superficial and deep perinei muscles, bulbocavernosus muscles and pubococcygeus muscles of both sides and also sphincter ani externus and the superior and inferior layer of urogenital diaphragm (together called triangular ligament).

Controversy about the Role of Levator Ani and Central Tendinous Point of Perineum

In the experience of Jeffcoate (1981) and many others, complete perineal tear with consequent diavirication of levator ani do not lead to development of either uterine or vaginal prolapse, not even rectocele.

The Reality about Pathological Anatomy/Etiology of Prolapse

The author proposes that in this disorder of displacement in majority of cases the anatomy is probably congenitally pathological, i.e. in most women who develop prolapse the supporting system of their reproductive tract is probably inherently weak. Any other etiological factors, e.g. trauma of repeated vaginal birth, menopausal atrophy or disruptive force of chronic severe stress, are just incidental insults unmasking or precipitating the prolapse. They are not the primary factors. Here is the logic behind the above proposition:

Points in Favor of Familial and Racial Factor

- Familial incidence of prolapse has been reported, and prolapse has been found to occur in sisters
- Chinese women have been found to have more sturdy pelvic floor
- Obviously, in nulliparous prolapse the cause is inherent weakness
- There are some known developmental anatomical features that favor occurrence of prolapse, e.g.
  - Short vagina
  - Deep pouch of Douglas
  - Axial uterus, i.e. axis of cervical canal and vaginal canal are (relatively more) in one line than at right angles (Fig. 17).

Points against Obstetrical Stretch Injury as the Dominant Cause

- Not all, only a small proportion of multiparous women develop symptomatic prolapse (laxity-yes). These women are perhaps the very women whose support systems were inherently weak. For others who do not develop prolapse, it is reasonable to assume that their support systems must have been strong enough to withstand the stress
Jeffcoate\(^2\) found prolapse often follows easy rather than difficult labor pointing to some inherent pre-existing factor.

While it is true that 90% prolapse patients are parous; over 80% middle aged women are parous in any case\(^2\).

Current trend of allowing second stage of labor to prolong even up to 6 hours (under epidural analgesia) is testimony that stretch injury cannot be a very significant factor.\(^6,9\)

**Points against Menopausal Atrophy of Support as the Primary Case**

While this biological change occurs in 100% women, severe prolapse (not mere laxity) occurs only in a small percentage, i.e. perhaps only in those whose supports were already inherently weak.

**Points against the Factor of Chronic Stress as the Primary Cause**

Mere chronic stress succeeds in causing prolapse only when it is of severe degree and usually in those women whose supporting system was already inherently off the mark.

**Would Routine Prophylactic Forceps/Vacuum or Elective Cesarean Prevent Prolapse and Pelvic Floor Dysfunction?**

The idea here is not to stress the perineum. Here is what the literature says about it—“Because elective episiotomy and operative vaginal deliveries have not been shown to be beneficial, and potential harm is great, use of these procedures should be avoided when possible.”\(^10\)

If all women underwent cesarean section, there would undoubtedly be less future pelvic floor dysfunction. However, most women do not develop pelvic floor dysfunction.

A policy of elective CS would subject many women to a potentially dangerous procedure to prevent a condition that they never would have developed.\(^10\)

**Some Recent Findings about Pathological Anatomy of Prolapse**

- Biopsies of puborectalis muscle taken during operation for prolapse have demonstrated dystrophic type of lesions in the muscle and also structural change of neurogenic origin.\(^2\)
- EMG studies done on pelvic floor muscles in patients with prolapse showed tracings suggestive of neurogenic myopathy.\(^3\)
- Studies of sacral potential have demonstrated (in patients with stress incontinence)—prolonged latency in reflex response to stimuli.\(^3\)
- Operation of anterior fixation of uterus has been found to cause enterocele by exposing the pouch of Douglas to the expulsive forces.
- Anterior colposuspension (Burch’s operation) has been found to promote severe uterine prolapse within a very short time.\(^3\)

**REFERENCES**

INTRODUCTION

Considerations of etiopathology, incidence, clinical features and investigations as described in the previous chapter will provide a basis for management. This is essentially surgical unless unwillingness or unfitness prevent surgery, which includes exercises, palliative and medical treatment. It is important to recognize that the asymptomatic patient cannot be made to feel better by medical or surgical therapy. A corollary could be one cannot assess the success of therapy without comparing signs and symptoms before and after therapeutic intervention.

Surgical treatment becomes pointless if risk factors are not identified and modified. Belief that the treatment ends with surgery must be changed. Obesity, heavy lifting, constipation and pelvic floor muscle atrophy are among other factors that need to be addressed. If these are not, we are putting our patients right back into same situation and environment that contributed to their condition.

The crucial undertaking is to correctly define and assess the descent of the uterus and/or vaginal wall, and the herniation of genital and abdominal organs. Unlike hernias elsewhere (where functional consequences are minimal), pelvic support defects are commonly associated with alteration in bladder, bowel and sexual function. Prolapse of the bladder (cystocele) or urethra (urethrocele) through the anterior vaginal wall and/or prolapse of intestines (enterocele) or rectum (rectocele) through the posterior vaginal wall can be associated with uterine prolapse. Vaginal wall prolapse can occur without prolapse of the uterus, but uterine prolapse is invariably associated with vaginal wall prolapse. It is necessary to establish the presence or absence of cystocele, rectocele, urethrocele, paravaginal defect, SUI, procidentia principally, and then ascertain the degree and combination. What is always present in true procidentia is the enterocele.

As a recent advance, understanding of anatomy and physiology of supports of uterus is better, as is the knowledge about compromise of pelvic floor, muscle, connective tissue and nerve, by vaginal childbirth, especially if prolonged. There are three mechanical principles, which explain how the uterus and vagina are normally held in place:

1. The uterus and vagina are attached to the walls of pelvis by the endopelvic fascia that suspends the organs from the pelvic sidewalls.
2. The levator ani muscles constrict the lumina of these organs until they are closed, forming an occlusive layer on which the pelvic organs can rest.
3. Third supportive effect called a flap valve results from the above structural arrangements. With the vagina suspended in such a way that it rests against the supporting wall adjacent to it, increases in pressure force the vagina against the wall, thereby pinning it in place.

The top layer of the pelvic floor is created by the endopelvic fascia, which attaches the pelvic organs (especially the vagina and the uterus) to the pelvic walls, thereby suspending them. This is a viscerofascial layer. The part that attaches to the uterus is called “parametrium”, and that which attaches to the vagina is called paracolpium. The parametria are made up of what we refer to as the Mackenrodt’s ligament and uterosacral ligament. The paracolpium is responsible for suspending the apex of vagina after hysterectomy (level 1 according to DeLancy).
The function of the levator ani muscles can be compromised in two ways. First, there can be a direct injury to the muscle resulting in mechanical disruption of the entire muscle. Second, damage to the nerve supply of the muscles can lead to their inability to contract, even though they themselves remain intact. As small nerves are torn away from their muscle fibers, the ability of the muscle to contract is diminished and normal function is lost.

For the pelvic muscles to support the pelvic organs, they must not only have their normal structure, but must also have intact sensory and motor innervation. The recognition that neurologic damage occurs during child birth is one of the science's significant contributions to the study of pelvic floor.

Etiopathology of prolapse in relation to management also encompasses congenital weaknesses of supports of uterus and estrogen deficiency. In young women in the childbearing age group, a single vaginal delivery may be followed by the unremitting load of abdominal pressure that stresses them.

Epidemiologic studies point to vaginal delivery as the strongest risk factor, although the etiology is multifactorial. The pathophysiological mechanism of prolapse have not been fully elucidated, but it is likely that damaged or malfunctioning skeletal muscle, smooth muscle, connective tissue and nerves all play a role in the progression of this disease.

**Site-Specific Defect Theory**

Support for the site-specific defect theory (SSDT).

Advocates of the SSDT changed the definition of enterocele to an area in the vagina (typically at the apex) where there is a gap between the anterior pubocervical fascia and the posterior rectovaginal fascia. In this site, the peritoneum comes in contact with the vaginal wall epithelium. This could be identified surgically and repaired by suturing pubocervical fascia to rectovaginal fascia.

**POSTHYSTERECTOMY APICAL PROLAPSE**

Posthysterectomy apical prolapse was felt to represent detachment of the vaginal apex from the uterosacral ligament.

Here repair emphasizes the ipsilateral attachment of the vagina to the uterosacral ligaments without plication of the uterosacral ligaments across the midline.

Shull reported a greater than 90% success rate in the treatment of apical vaginal vault prolapsed with vaginal site-specific enterocele repair and uterosacral "ligament suspension".

Laparoscopic site-specific fascial defect repair of enterocele in vaginal apex prolapse showed an 88% success rate at 6 month follow-up.

**RECTOCELE**

Rectocele was newly defined as a gap in the rectovaginal fascia where the rectum comes in contact with the vaginal wall epithelium. Various breaks or detachments of the rectovaginal fascia were identified at gross surgical dissection and repaired individually. Reconstruction of the perineal body was also emphasized. Narrowing of the levator hiatus is not performed in the surgical case series documenting outcomes of site-specific rectocele repairs.

**CYSTOCELE**

If the anterior vaginal wall is prolapsed and there was a detachment laterally at the arcus tendineus fascia pelvis, then lateral support of the vagina with sponge stick will correct the cystocele. If there is primarily a midline tear in the anterior vaginal wall, the vaginal wall epithelium overlying the muscularis will be stretched and there will be loss of the rugated appearance of the epithelium. Richardson documented a greater than 90% success rate when repairing...
anterior vaginal wall prolapse and stress urinary incontinence by this approach.

CONCLUSION

Site-specific defect theory of POP has helped to advance our concepts about the etiology and surgical repairs. Unfortunately, parts of this theory have been proven inaccurate by current studies.

Most women with POP have both neuromuscular injury and connective tissue injury to their pelvis. Proponents of site specific defect have underemphasized the neuromuscular injury component, later part of which may be responsible for the high recurrent rate of POP. Proper evaluation of “defects” and incorporation of new procedures is now essential. Probably, further prospective evaluation might answer this theory of “site-specific repair”. Adequate stress should be given to the patient’s perspective in this evaluation, taking her bladder, bowel and sexual function into account apart from correction of prolapse.

The precipitating factors are:
- Repeated unsupervised/home deliveries
- Precipitate delivery
- Prolonged second stage of labor
- Instrumental delivery, especially before cervix is fully dilated
- Strenuous work in farms like lifting heavy weight or prolonged work in squatting position
- Chronic cough or chronic constipation
- Chronic anemia and malnourishment
- Increased intra-abdominal pressure due to tumor or ascites.

Certain associated conditions should always be noted, ruled out or treated before surgery.
- Genuine stress incontinence (GSI)
- Urinary tract infection (especially cystitis)
- Any other associated organic pathology, e.g. fibromyomata, endometriosis, Ca cervix, adnexal pathology (ovarian tumor)
- Pelvic inflammatory disease
- Decubitus ulcer
- Vulval or perineal pathology.

All conditions mentioned above modify the treatment of prolapse.

INVESTIGATIONS

Thorough examination is done before surgery. Hemogram, blood group with Rh, urine analysis with culture and sensitivity, Pap smear, intravenous pyelography (IVP), X-ray chest. Sonography should be a mandatory modern investigation as it rules out adnexal, other pelvic organic pathologies and pyometra (rare but important). Sonography would also rule out any associated kidney, ureteric, bladder or abdominal pathology. Sophisticated investigations like urodynamic studies, visecrograms, colpocystograms, defecography, dynamic fluoroscopic pelvic floor evaluation, advanced USG and MRI are relevant but not routinely possible. Investigations to establish fitness for anesthesia/surgery are essential.

POINTS TO REMEMBER

Preoperative

- Prior medical treatment of chronic cough/chronic constipation is a must.
- Presence of decubitus ulcer on the cervix could mean altered vascularity and associated infection, which needs treatment with glycerine-acriflavine pack or ring pessary. Both help by repositing the uterus to its normal anatomical position, thus relieving kinking of uterine vessels, cervical congestion and ulcer formation. The surgical procedure should be delayed till the congestion and infection around ulcer show arrest or regression. This will reduce excessive intraoperative bleeding and flaring up of infection postoperatively.
- Associated urinary tract infection and pelvic inflammatory disease (PID) must be treated aggressively.
- Preoperative estrogen therapy should be given to patients, especially the elderly, where the vaginal epithelium is very thin and inflamed.
- Antiseptic vaginal douches not less than a day before surgery.
- Full dose of antibiotics 2 hours before surgery to be given IV (e.g. 1 gram ampicillin, 80 mg gentamicin, 500 mg of metronidazole) to prevent incidence of postoperative pelvic infection.
- In diabetic cases, a higher antibiotic (Cefotaxime, Ciproflaxcin) may be considered.

Intraoperative (for Vaginal Operations)

- Thorough painting of vagina, vulva, perineum, medial aspect of thighs and lower abdomen.
- Proper vulval retraction with skin stitches.
- Keeping anal canal away by stitching fourchette with drape.
- Adequate illumination with addition of fiber optic directed cold light is desirable.
- Infiltration of pericervical and forniceal areas with normal saline alone, or with adrenaline, if the patient is not hypertensive, to facilitate dissection in proper plane and reduce intraoperative bleeding.
- Proper identification of lower limit of the bladder using a metal catheter/bladder sound.
- Use of 1.0 vicryl for pedicles.
- Use of chromic catgut 1 for vaginal suturing.
- Proper hemostasis at every step of the operation.
- retracting the anterior vaginal wall with Sim’s speculum provides excellent exposure of the posterior peritoneum.
Now, enterocele repair is ensured by closing the peritoneum as high as possible at a level identified by extraperitoneal pad of fat.

- Forming a good trough by tying opposite pedicles together especially the uterosacral ligaments. The opposing uterosacras should be further united by insertion of two sutures along their length posteriorly. In effect, the gap between them is closed for prevention of future enterocele.
- At this juncture, encerclage of the uterosacrals by these sutures should be scrupulously avoided to prevent ureteric injury or kinking.
- The uterosacral sutures are to be anchored to the vagina for vault suspension.
- While repairing cystocele, avoid excessive dissection into paraurethral, paravesical or retropubic spaces to avoid damage to the venous plexuses.
- Bladder neck is to be supported by a buttress stitch such as Kelly’s to treat stress incontinence if present or to prevent its iatrogenic occurrence (2–3%).
- To rest the bladder for 2 days after cystocele repair and for 3–5 days after Kelly’s stitch with self-retaining catheter.
- While a minimal rectocele may be required, over-enthusiasm should be avoided when tightening relaxed perineal outlet, otherwise dyspareunia will result.
- Dissection of rectum to be gentle, careful and slow even if deemed easy.
- Perineorrhaphy for lax perineum is best done by approximating both levator ani bellies together with #1 PGA sutures. Beware of rectal injury at this step.
- Frequently, bleeding is encountered during colpoperineorrhaphy, so proper hemostasis is to be ensured at each stage. Diathermy can be advantageous or complicating.
- Vaginal pack (optional ?), retained up to 24 hours, is advantageous to prevent inevitable oozing.
- Examination per rectum at the conclusion of procedure is mandatory.

Postoperative

- Sedatives and analgesics as per requirement, generous if required and permissible
- Antibiotic cover for 7 days
- Metronidazole for 48 hours
- Early ambulation
- Plenty of fluids orally
- Early feeding with semisolids and solids
- Repeat hemogram, PCV, urine examination routine at 48 hours
- The issue of early discharge should be individualized.

**Surgical Procedures**

Various surgical procedures can be classified as shown in Table 1.

<table>

<tr>
<td>3. Laparoscopic</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The choice of the surgical procedures depends on the following:

- Age
- Desire for further child-bearing
- Desire for preservation of menstruation
- Degree and type of prolapse
- Degree of cervical elongation
- Associated organic/adnexal pathology
- Associated medical/surgical problem.

*It is beyond the scope of this article to go into the details of every surgical procedure. Some are briefly described for their principles, applicability, popularity, results, reporting and evaluation in the Indian context. Each procedure should be discussed at length with the patient, explaining the advantages and disadvantages. Proper counseling should enable the patient to make her own decision and provide informed consent.*

**Conservative Techniques for Very Old, and Especially Those Unfit for Major Anesthesia**

**Le Fort’s Operation**

It was deemed an operation of choice.

**Dani’s Stitch** *(Introital Tightening)*

It is easier and simpler than Le Fort’s operation. It is a simple minor procedure and can be performed under local anesthesia. Slightly increased risk of SUI after this stitch can be minimized by proper suburethral placement of the stitch to lift the urethra slightly. Initially, #1 monofilament nylon was used. The occurrence of the stitch cutting through was subsequently minimized by local estrogen therapy preoperative and postoperative, use of polylactic acid material (Vicryl #1 or 2) and going sufficiently deep in tissues around the introitus.

**Conservative Techniques for Young Patients**

**Vaginal**

*Fothergill’s operation* *(Manchester repair): This operation is an option in a wide age group where the patient desires preserving organ function. It can correct prolapse up to second degree. It consists of amputation of cervix and shortening of Mackenrodt’s ligaments along with anterior colporrhaphy and/or posterior repair. This operation was initially advocated for young women who were desirous of
child-bearing. Also, it is an operation of choice when cervical elongation and/or chronic cervicitis is present. However, cervical amputation may adversely affect subsequent conception (infertility, cervical stenosis) and/or pregnancy outcome (repeated second trimester abortions, preterm labor, cervical dystocia or precipitate labor). For these reasons, this repair is not considered as an operation of choice in India. However, techniques avoiding cervical amputation, viz. modified Fothergill’s or Shirodkar modification of Fothergill’s can be considered.

Abdominal

These consist of various types of sling operations.

Shirodkar’s Posterior Sling Operation

This operation is a “milestone” in the surgery for prolapse, perhaps a “gold standard”. Newest techniques are based on his principle that the uterosacral ligaments are the most important supports of uterus. This ligament not only holds the uterus at a higher level, but also maintains it in an antverted position. Mackenrodt’s ligaments hold the uterus up but their role in keeping uterus antverted is doubtful. Therefore, Shirodkar designed his operation by creating artificial uterosacral ligaments. The difficult part of his surgery was the left sided sling where a psoas hitch has to be formed. It has inherent potential for complications like injury to ureters, major vessels, genitofemoral nerves and the sigmoid.

Soonawala’s Unilateral Posterior Sling Surgery

We reproduce the originator’s personal communication below.

In case of nulliparous prolapse or prolapse in parous young women where function of the uterus is to be preserved, vaginal approach is not suitable for surgical correction as the results are not satisfying. Abdominal approach to fortify the uterosacral ligaments is one procedure which gives excellent results. A number of variations of this are described. The technique described here is simple, easy to perform and has given excellent results with low recurrence rate. It strengthens the main support of the pelvic fascia responsible to keep the uterus in its normal antverted position and preventing its descent.

Procedure: By a Pfannenstiel incision, the abdomen is opened and bowel loops are packed to give the pelvic cavity a good exposure. Promontory is identified and peritoneum over the first sacral vertebra is incised, fibroareolar tissue is dissected to visualize the anterior longitudinal ligament. Prolene loop, a special suture which is two strands of No. 1 prolene on a large atraumatic needle, is used. This is anchored to the anterior longitudinal ligament. The needle is then passed extraperitoneally along the right uterosacral ligament to the isthmus of the uterus taking a bite of the uterine wall. The path is retraced extraperitoneally to come into the area of the first sacral vertebra. The two ends are tied back securely pulling the cervix of the uterus up toward the sacrum. The incised peritoneal edges are apposed and abdomen is closed in layers.

Conclusion: For second and third degree uterine prolapse where function of the uterus is to be maintained, procedure to fortify the anatomical uterine support, uterosacral ligament, is most satisfying. Since the supporting sling does not encircle the uterine isthmus, it does not restrict dilatation of the cervix and normal delivery can take place. It does not constrict the rectum as it is only on the right side of the pelvis. Mersilene tape can be advantageously substituted for prolene loop.

Purandare’s Cervicopexy

Here, slings are formed from the rectus sheath and fixed on the anterior surface of the uterus near isthmus.

Disadvantages of this operation are:
- It does not cause effective anteversion of the uterus.
- Interference with vaginal delivery.
- High recurrence rate, because the slings can get stretched and attenuated with age.
- If cesarean section is required, the sling has to be incised.

Joshi’s Sling

Through a Cherney incision, the uterus is suspend-
ed to the pectineal ligament on both sides with Mersilene tape. Burch colposuspension can be done in selected cases.

Technique: Using a stout curved Mayo needle, Mersilene tape is anchored as its midpoint to the anterior surface of the uterus just above the level of internal os. A long artery forceps is passed subperitoneally from the retropubic space, just below the lateral end of the round ligament, toward the lateral edge of the peritoneal incision over the uterus, to grasp the lateral end of the Mersilene tape on that side. Lateral end of the tape is now drawn to the retropubic space. This procedure is repeated on the other side. Threaded into a curved cutting Mayo needle, the lateral end of the tape is passed through adequate thickness of pectineal ligament on each side as laterally as possible. The two ends of the tape are now drawn taut to elevate the uterus adequately and are anchored to the pectineal ligaments using 3 or 4 knots. The knots are fixed with “0” prolene sutures to prevent loosening and the excess portion of the tape is cut-off. This results in anteflexion and elevation of the uterus.

Comments
- The uterus is effectively elevated without compressive effect on any organ.
- The weight of the uterus is shared by two strong ligamentous anchoring points minimizing the chance of recurrence.
The technique involves minimal dissection away from structures like ureter, rectosigmoid, and median sacral vessels.

Most patients deliver vaginally and cesarean can be done without cutting the tape.

**Virkud’s Sling**

Here, one end of the Mersilene tape (30 cm long) is fixed to the sacral promontory posteriorly with two strong linen stay sutures. It is then passed subperitoneally on right side of pelvic wall, then through broad ligament and fixed to posterior surface of the isthmus of the cervix with # 20 Barbour linen stay sutures. The tape is then passed between left broad ligament through left internal inguinal ring, piercing the transversalis fascia and turned medially at linea semilunaris between the rectus muscle and sheath, where it is sutured with # 20 Barbour linen to rectus sheath. The left uterosacral ligament is then plicated with linen, in order to correct the dextrorotation of the uterus. According to the author this helps in maintaining anteversion. The advantages of this operation are: it provides a double support, *static:* bone (sacral promontory), *dynamic:* rectus sheath. It is technically easier to perform and being an open sling, there is no risk of bowel obstruction later on.

In fact, this operation is a combination of Shirodkar’s posterior sling on right side, and Purandare’s sling on the left side.

**Khanna’s Sling**

In this operation the tape is fixed posteriorly to the isthmus with three sutures of # 4.0 black silk. With the help of uterine packing forceps, one end of this tape is drawn laterally across the iliac fossa retroperitoneally between the leaves of the broad ligament. Same step is repeated on the other side. Two ends of the tape are held tight, buried and sutured to the lateral end of the inguinal ligament close to the anterior superior iliac spine. # 3.0 black silk suture is used and care is taken to leave the knots deeper to the inguinal ligament. The author claims that this works like a transverse cervical ligament (Mackenrodt’s ligament) and therefore not only elevates the uterus but also maintains anteversion.

All components need proper identification and adequate correction.

**Causes**

- Missing the diagnosis of enterocele preoperatively.
- Failure to take due precautionary steps to support the vault in surgical technique during hysterectomy.

Higher closure of the posterior peritoneum and suturing both the uterosacral ligaments to each other and then to the vault with vicryl are the two most important steps to prevent vault prolapse.

Prophylactic sacrospinous fixation of the vault at the end of vaginal hysterectomy for prolapse has been practised and advocated.

**Management of Vault Prolapse**

It is essentially surgical, either vaginal or abdominal.

**Vaginal Colpoplasty**

This consists of dissection, plication of enterocele with anterior and posterior vaginal wall repair. Support of the vault with uterosacral is an integral part of the repair. However, the uterosacral are difficult to identify and may not be strong enough to give lasting support.

- It can be difficult due to fibrosis.
- Injury to the rectum and bladder may occur.
- Loss of vaginal coital potential.

**Sacrospinous Colpopexy: Commonly Unilateral**

It involves dissection of pararectal space, identification of sacrospinous ligament and suspension of the vault using # 1 prolene aided by special instruments like Miya hook.

**Advantages**

- Vaginal axis and coital potential are maintained.
- Low recurrence rate.

**Disadvantages**

- It involves many blind steps which may predispose to injury to pudendal nerve and vessels, sacral nerves, rectum and ureter.
- Technically difficult in recurrent vault prolapse because of fibrosis and shortened vagina.

**Abdominal route**

- Sacral colpopexy using prolene or Marlex mesh.
- Soonawala’s sling: as discussed previously.
- Joshi’s unilateral vault-pectineal suspension: posterior culdoplasty is mandatory.
- Endoscopic vault suspension has been reported recently with encouraging results.
**Laparoscopic Surgery for Repair of Pelvic Floor Defect**

One of the primary goals of laparoscopic reconstruction is to reproduce proven abdominal techniques in a minimally invasive way without compromising safety or efficacy. Compromising traditional surgical technique for the sole purpose of accomplishing the repair laparoscopically should be discouraged. A laparoscopic procedure may not be appropriate if there is history of a multiple abdominal surgery or pelvic infection (e.g., ruptured appendicitis, pelvic inflammatory disease) suggesting the presence of adhesion. Transvaginal surgery may be preferred in elderly, obese and other high-risk situations where general anesthesia should be avoided.

The surgical techniques which are employed laparoscopically are:

- Paravaginal repair for cystocele.
- Uterosacral ligament uterine suspension and sacrocervicopexy for management of uterine prolapse.
- Sacrocolpopexy for treatment of vaginal eversion.
- Enterocoele repair.

**Complication:** Vascular and bowel injury are most common complications during access in any laparoscopic procedure. Injury to urinary tract is an additional complication of procedure for repair of pelvic floor defect. Intraoperative cystoscopy should be a routine part of the surgery.

**William-Richardson’s Operation**

Here, a strip of external oblique aponeurosis is dissected free, brought inside the abdominal cavity extraperitoneally and fixed to the lateral fornices of vagina with the linen or silk suture so as to elevate the vault of vagina.

**Posterior Intravaginal Sling Plasty (IVS)**

This minimally invasive transperineal technique developed by Petros aims at restoring the three anatomical levels of vaginal support described by Delaney. It involves the implantation of tension-free polypropylene tape to create an artificial uterosacral neo ligament for the support of vaginal vault prolapse. In short-term follow-up 91% cure rate has been reported.

**Surgical Principles of Suture Materials**

Collagen is central to wound healing and the weaker more elastic type III is laid down first. With maturation, type I replaces type III, but the new tissue is never as strong as original. Fascia will only have regained 15% of its original strength by 14 days and takes 3 months to regain 70%. However, the most common suture material used for vaginal repair is rapidly absorbable such as polyglycolic acid and polyglactin. Hence, first principle, tells surgeons to use a longer acting material. Gynecologists are slow in utilizing the newer synthetic sutures now available. Only delayed absorbable sutures should be used, though more data on suture material in pelvic reconstructive surgery is required.

**THE USE OF PROSTHETICS IN PELVIC RECONSTRUCTIVE SURGERY**

With a reoperation rate of 30% for prolapse surgery attempts are being made to improve the outcome of primary surgery. The introduction of synthetic and biological prosthesis has been proposed to reduce recurrence rate whilst maintaining vaginal capacity and coital function.

There is growing opinion that conventional surgery for prolapse without a graft is like attempting to repair damaged tissue with poor vascular supply, predisposing to surgical failure.

**CLASSIFICATION**

I. Synthetic material

1. Macroporous, nonabsorbable (e.g., Marlex, Prolene): The pore size is more than 75 nm to allow infiltration by macrophage fibroblast, new vessels and collagen fibers. They are mainly used for prolapse surgery. The problem is mesh erosion.

2. Absorbable-polyglactin (vicryl): No complication of mesh erosion; however, long-term results are doubtful.

II. Biological material

1. Autologous materials include rectus fascia, fascia lata.

2. Xenografts may be porcine: New prosthetic systems have been introduced for the management of vaginal prolapse, e.g., (1) posterior intravaginal sling plasty; (2) apogee/perigee.

**Mesh Erosion**

The risk of erosion is one of the factors that have made the use of synthetic prosthesis controversial. The management of erosion depends on amount of mesh exposed, the type of material and associated infections.

Erosion presents with vaginal discharge, bleeding, pain and dyspareunia. Initially topical estrogens (in postmenopausal women) and broad spectrum antibiotics can be tried. Small erosion less than 5 mm may be closed with this management alone. If this fails or if erosion is up to 2 cm in size surgical recovering is required. For erosions more than 2 cm, removal of prosthesis and reapproximation of vaginal tissue is required.

*Every honest surgeon of extensive and long experience will have to admit that he is not entirely and absolutely satisfied with his long-term results of all his operations for prolapse and allied conditions.*

—Richard TeLinde
The corollary could be the surgeon is satisfied but the patient is not, very rarely, the patient is satisfied but the surgeon is not. Together, the first chance is the best.

—Authors

REFERENCES

For the past two decades, Obstetricians and Gynecologists have strongly advocated discontinuing the use of the term “pelvic inflammatory disease” (PID). In the initial conceptualization, PID was used to designate upper female genital tract infection caused primarily by Neisseria gonorrhoeae. Centers for disease control (CDC) definition of PID is “PID comprises a spectrum of inflammatory disorders of the upper female genital tract, including any combination of endometritis, salpingitis, tubo-ovarian abscess and pelvic peritonitis”.

In November 1999, the International Infectious Disease Society for Obstetrics and Gynecology—USA (IIDSOG—USA) formed a 7-member panel to address growing concerns regarding this disease entity. The recommendations put forward by the panel were subsequently reviewed and approved by the society. The society recommended to use the term “upper genital tract infection” (UGTI) instead of “PID”. Recognizing how ingrained the term PID is and the massive education effort required to effect a change, an interim solution was proposed. For the term “PID” to be used the following criteria need to be fulfilled:

Anatomic designation: Disease must involve at least the endometrium and Fallopian tubes (Figs 1A to C).

Causative designation: The term is restricted to disease in which the primary causatives are major sexually transmitted disease microorganisms that share common demographic features and consequences. Organisms taking part via superinfection would be addressed in the recommendation on staging of the disease. For bacteria (such as Streptococcus pneumoniae or Group A Streptococcus) that on rare occasions fulfill the anatomic requisites, the diagnostic designation would be “UGTI due to relevant bacteria”.

Pelvic inflammatory disease is defined as the inflammation of upper genital tract organs typically involving the Fallopian tubes, ovaries and surrounding structures. According to the IIDSOG—USA, the PID is defined as “an inflammatory process of infectious etiology which shares a common epidemiological profile (sexual risk factors), which specifically involves at least the uterine and/or Fallopian tube sites, and which may result in relatively comparable long-term sequel. Disease due to bacteria not meeting these requirements will be termed UGTI and the designation of specific etiology cited”. The society also approved the following staging of acute PID. The necessity of the staging is to implement a rational and appropriate therapeutic regimen.

- **Stage I**: Patients who fulfill the CDC major diagnostic criteria with one or more of its minor criteria but do not have overt peritonitis, as demonstrated by the absence of rebound tenderness, and have not had a prior documented sexually transmitted UGTI.
- **Stage II**: Patients who meet the above criteria but who have peritonitis.
- **Stage III**: Patients with demonstrable tubo-ovarian complex/tubo-ovarian abscesses by either physical or USG examination.
- **Stage IV**: Patients who have ruptured tubo-ovarian abscess.

**CAUSATIVE ORGANISMS**

Sexually transmitted organisms, especially *N. gonorrhoeae* and *Chlamydia trachomatis* are implicated in most cases; however, microorganisms which are usually part of vaginal flora (e.g. anaerobes, Gardnerella vaginalis, Haemophilus influenzae, enteric Gram-negative rods and *S. agalactiae*) can also cause PID. In addition *Mycoplasma hominis* and *Ureaplasma urealyticum* may also be causative organisms.
PREVALENCE

Being the main gynecological cause of acute lower abdominal pain, PID has a prevalence of 9–27 per 1,000 fertile women.  

DIAGNOSTIC CONSIDERATIONS

Due to the wide variation of symptoms and signs, acute PID is difficult to diagnose. Delay in diagnosis and also initiation of treatment leads to inflammatory sequel in the UGT. Goal of diagnosis is to establish guidelines that are sufficiently sensitive to avoid missing mild cases but at the same time sufficiently specific to avoid giving antibiotic therapy to women who are not infected.  

Laparoscopy has been considered the gold standard for PID diagnosis, but its sensitivity varies depending on the stage of illness—being less sensitive in the mild form, where diagnostic criteria are less objective.  

So PID diagnosis is based on certain clinical criteria proposed in 1983 and modified in 1991. Data indicate that positive predictive value of a clinical diagnosis is 65–90% compared with laparoscopic diagnosis. In all settings, however, no single historical, physical or laboratory finding is both sensitive and specific for the diagnosis of acute PID. Combinations of diagnostic findings that improve either sensitivity or specificity do so only at the expense of the other. For example, requiring two or more findings excludes more women who do not have PID but at the same time reduces the number of women with PID who are identified. Because of the difficulty in diagnosis and potential for damage to the reproductive health of women, by even apparently mild

Figs 1A to C: Modes of causation of pelvic inflammatory disease
cases, health care providers should maintain a low threshold for the diagnosis of PID.

**CRITERIA FOR THE DIAGNOSIS OF ACUTE PID (CDC, MAY 2002)**

**Minimum Criteria**
Uterine/adnexal tenderness or cervical motion tenderness.

**More Elaborate Criteria**
These additional criteria may be used to enhance the specificity of minimum criteria.

- **Routine criteria for PID diagnosis:**
  - Oral temperature greater than 38.3°C or 101°F
  - Abnormal cervical or vaginal mucopurulent discharge
  - Raised ESR
  - Increased C-reactive protein
  - Laboratory documentation of cervical infection with *N. gonorrhoeae/C. trachomatis*
  - Presence of WBC in saline preparation of vaginal secretion

- **Specific criteria for PID diagnosis:**
  - Histopathological evidence of endometritis in endometrial biopsy
  - TVS/MRI showing thickened fluid filled tubes with or without free pelvic fluid or tubo-ovarian complex or Doppler studies suggesting pelvic infection (e.g. tubal hyperemia). Laparoscopic abnormalities are consistent with PID.

**RISK FACTORS FOR ACUTE PID**
- Multiple sexual partners
- Past history of sexually transmitted infection (STI)/PID (Westrom and Eschenbach, 1998)
- Vaginal douching (Westrom and Eschenbach, 1998)
- Use of drugs or alcohol, especially with sexual activity
- Lack of consistent condom use
- Lack of contraceptive use (oral contraceptive and DMPA are protective against PID not STI (Speroff, Glass and Kase, 1999)).

**PREVENTION OF PID**
Theoretically, the majority of PID cases can be prevented by screening all women at high risk (based on age or other factors) by using DNA amplification on cervical specimens (in women receiving pelvic examination) and on urine specimens (in women not undergoing pelvic examination). Although bacterial vaginosis (BV) is associated with PID, it is not clear whether treatment of BV can reduce the incidence of PID.

**SEQUELAE OF PID**
- Infertility
- Ectopic pregnancy
- Chronic pelvic pain

**DIFFERENTIAL DIAGNOSIS**
- Ectopic pregnancy
- Appendicitis
- UTI and pyelonephritis
- Constipation
- Gastroenteritis
- Rupture, bleeding or torsion of an ovarian cyst
- Mittelschmerz
- Inflammatory bowel disease (rare)
- Renal colic (rare).

**INVESTIGATIONS**
- Complete blood count
- Urine pregnancy test
- High vaginal swab
- DNA Polymerase Chain Reaction
- Ultrasonography
- Laparoscopy
- Endometrial biopsy

**TREATMENT**
Treatment regimens for PID must provide empiric, broad spectrum coverage of likely pathogens. Several antimicrobial regimens have been effective in achieving clinical and microbiologic cure in RCT and short-term follow-up. However, only a limited number of studies have assessed and compared these regimens with regard to elimination of infection from the endometrium and Fallopian tubes or estimated the incidence of long-term complications (e.g. tubal infertility and ectopic pregnancy) after antimicrobial regimens. Need to eradicate anaerobes from women who have PID has not been determined definitely. Anaerobic bacteria have been isolated from UGT of women with PID and in vitro studies have revealed that some anaerobes (e.g. *Bacteroides fragilis*) can cause tubal and epithelial destruction. Until treatment regimens that do not adequately cover these microbes have demonstrated to prevent long-term sequel as successfully as the regimens that are effective against these microbes, the use of regimens with antianaerobic activity should be considered. The physician should take into account the cost, availability, acceptance and susceptibility of the medicine while selecting a treatment regimen.
TREATMENT REGIMENS
(RCOG GUIDELINES 32, MAY 2003)

Outpatient Treatment (Grade B Recommendation)

Oral ofloxacin 400 mg bid + oral metronidazole 400 mg bid × 14 days
OR
Intramuscular (IM) ceftriaxone 250 mg stat or IM cefoxitin 2 g stat with oral probenecid 1 g, followed by oral doxycycline 100 mg bid + oral metronidazole 400 mg bid × 14 days.

In-Patient Treatment

Criteria for Hospitalization (CDC 2002)

• Surgical emergency cannot be ruled out
• Pregnancy
• No clinical response to oral antibiotic therapy
• Inability to follow or tolerate an outpatient oral regimen
• Severe illness, nausea, vomiting or high fever
• Tubo-ovarian abscess.

Inpatient therapy is based on IV regimens which should be continued until 24 hours after clinical improvement and followed thereafter by oral therapy.

Recommended Parenteral Regimens (COG May 2003) (Grade B Recommendation)

IV cefoxitin 2 g tid + IV doxycycline 100 mg bid (oral doxycycline may be used if tolerated; doxycycline infusion in painful), followed by oral doxycycline 100 mg bid + oral metronidazole 400 mg bid for a total of 14 days.
OR
IV clindamycin 900 mg tid + IV gentamicin 2 mg/kg loading dose followed by 1.5 mg/kg tid (a single daily dose of 7mg/kg may be substituted), followed by either oral clindamycin 450 mg qd to complete 14 days oral doxycycline 100 mg bid + oral metronidazole 400 mg bid to complete 14 days.
OR
IV ofloxacin 400 mg bid + IV metronidazole 500 mg tid for 14 days.

If parenteral gentamicin is used, serum drug level and renal function should be monitored. Evidence of the efficacy of antibiotic therapy in preventing the long-term complications of PID is currently limited.

TREATMENT IN PREGNANCY
(RCOG, MAY 2003)

Pelvic inflammatory disease in pregnancy is extremely rare condition except in septic abortion. Treatment will depend upon organisms isolated. Drugs known to be toxic in pregnancy, e.g. tetracycline, should be avoided.

TREATMENT IN YOUNG WOMEN
(RCOG, MAY 2003)

Based on data on animal studies, it is said that ofloxacin should be avoided while bone development is still occurring. No problems have been reported in human subjects and the British National Formulary currently recommends ofloxacin in children where other options are limited. Doxycycline can safely be used in children greater than 12 years of age.

TREATMENT IN A WOMAN WITH AN INTRAUTERINE DEVICE

Grade B recommendation, RCOG 2003

An intrauterine device (IUD) may be kept in site in mild PID, but should be removed in severe disease. IUD increases the risk of development of PID only in the first few weeks after insertion.¹⁵

SURGICAL TREATMENT (GRADE B RECOMMENDATION RCOG 2003)

Surgical treatment is considered in severe cases or where there is clear evidence of a pelvic abscess. Help of laparoscopy or laparotomy may be taken for adhesiolysis or drainage of pelvic abscess. USG guided aspiration of pelvic abscess is less invasive and equally effective.

MANAGEMENT OF SEX PARTNERS

Male sex partners of women with PID caused by N. gonorrhoeae or C. trachomatis are often asymptomatic; so they should be examined and treated if they had sexual contact with the woman during the 60 days preceding the woman’s onset of symptoms. Sex partner should be treated empirically with regimens effective against both of these organisms, regardless of the etiology of PID or pathogens isolated from the infected women. Patients should be advised to avoid intercourse until they and their partners have completed the treatment schedule.

PID IN WOMAN WITH HIV

Contrary to the previous belief that HIV infected women get more severe PID, recent studies show that there may be minor differences and they respond equally well as of the women who are not infected with HIV.¹⁶

PID IN POSTMENOPAUSAL WOMEN

Pelvic inflammatory disease is a rare entity in this age group. Extragenital pathology in addition to genital tract malignancy
must be considered in these patients. Direct extension of infectious processes from adjacent intra-abdominal viscera is more likely to be associated with PID in older women. Forgotten IUD may be associated with a serious genital tract infection. Postmenopausal women are less likely to harbor a sexually transmitted organism than the premenopausal counterpart. In most reported cases the organisms frequently encountered were *Escherichia coli* (76%) and *Klebsiella* (43%). Other isolated bacteria included *Pseudomonas* (14%) and *Staphylococcus aureus* (< 5%). Broad spectrum antimicrobial therapy should be started and appropriate imaging studies obtained. Surgical intervention should be considered if there is no clinical improvement within 48 hours. Aggressive treatment in these seriously ill patients may lead to decrease in mortality and morbidity in this disease.

**FOLLOW-UP**

Patients should show definite clinical improvement within 3 days of starting of therapy. If it does not happen, she should be hospitalized and re-evaluated with the help of laparoscopy if needed (for alternative diagnosis) and parenteral therapy must be started. Some physicians advocate rescreening for *C. trachomatis* and *N. gonorrhoeae* 4–6 weeks after therapy is completed in women with documented infection by these pathogens (August 4, 2006/55 [RR 11]:1-94). All women diagnosed as acute PID should be offered HIV testing.

Ectopic Pregnancy: Current Concepts

INTRODUCTION

Ectopic pregnancy (EP) is an enigma, wrapped in mystery, presents in a bewildering variety of anatomical, physiological and clinical expressions. Natural course is equally unpredictable. While the medical fraternity grapples with unpredictability of the trophoblastic behavior, EP continues to be an important cause of maternal deaths. Just as the hyperactive trophoblasts rapidly invade the delicate tubal wall causing rupture and massive hemorrhage, the hypoactive ones remain treacherously dormant with a dangerous potential for fatal flare-ups. Mercifully, some of them resolve spontaneously, without bothering the clinician. EP thus is extremely difficult to diagnose early before tubal rupture.

Gupta and his colleagues (1992) observed that 60% had tubal rupture and only 4% had intact tubal gestation during surgery. Less than 50% conceived again and 12–18% reported with recurrent EP (Stabile et al. 1990). The incidence of EP is rising alarmingly “almost reaching epidemic proportions” (Makinen JI, 1987); a 4.5% increase has been observed in USA alone over the 70s (Ory, 1991). However, the case fatality rate decreased from 35.5 deaths per 10,000 cases in 1970 to 2.6 per 10,000 cases in 1992 (Sepilian V).

ETIOPATHOLOGY

Anything that hampers the migration of embryo to the endometrial cavity predisposes to ectopic gestation. Common conditions that increase the risk of EP include the following:

- **Pelvic inflammatory disease (PID):** Previous tube infections (salpingitis), risk EP 4-fold, the most common organisms are *Chlamydia trachomatis* followed by *Neisseria gonorrhoeae*. The successive attacks of PID increase the likelihood of another EP by 7–13 folds.
- **Prior history of tubal pregnancy** treated conservatively; there is a roughly 10-fold increase in tubal pregnancy.
- **History of tubal surgery and conception after tubal ligation:** 35–50% of patients who conceive after a tubal ligation are reported to experience EP.
- **Infertile subjects undergoing ovulation induction** with different ovulogens has been linked with a 4-fold increase in risk of EP with increased number of heterotopic pregnancy.
- **Salpingitis isthmica nodosum:** Microscopic presence of tubal epithelium in myosalpinx like small diverticula protrudes through tubes predispose to EP.
- **Other causative factors:** Intrauterine contraceptive device (IUCD) (3–4% risk), dermal-epidermal separation (DES) exposure, rupture appendix, etc.

CLINICAL PRESENTATIONS

Ectopic pregnancy has three distinct clinical groups:

1. **Acute:** Nearly one-fifth of all EPs require urgent intervention.
2. **Asymptomatic high-risk:** Less than one-fifth constitute this group; with history of impaired tubal function, previous tubal surgery, previous EP and infertility cases undergoing ovarian hyperstimulation in assisted reproductive technology (ART), etc. As they become biochemically pregnant, they are screened, followed up and managed very early before symptoms develop (Ankum et al. 1996). Refer to Table 1 for important landmark.
3. **Subacute cases:** Nearly 60–70% constitutes this major group. They present with or without amenorrhea, irregular vaginal bleeding and abdominal pain. For the rest of our discussion, we will focus our attention on the last two groups of EPs, which are most difficult to diagnose early.
CURRENT DIAGNOSTIC APPROACH

The focus now is on an awareness to detect not only EPs early, but to follow them in a controlled way, monitoring blood concentration of β-hCG under sonographic guidance. The objective is to treat the patients with minimal invasive surgery or without the aid of laparoscopy using medicine and to send them back to their normal day-to-day life at the earliest directed to restore tubal function. Application of serial quantitative β-hCG concentration correlating with the first sonographic appearance of intrauterine pregnancy (IUP) (discriminating zone) further helped early detection. The potential diagnostic dilemma was further eased with the use of high-resolution TVS. To understand this intricate pathophysiology we focus our attention what happens in normal pregnancy.

Serum β-hCG Level in Normal Pregnancy

Human chorionic gonadotropin is a glycoprotein secreted by the trophoblasts in the body; contains alpha and beta subunit. The serum testing for beta subunits is more accurate. As the pregnancy grows, exponential rise in hCG level takes place, becomes double every 60 hours (roughly 2 days) and attains the peak by eight menstrual week followed by slow declines. A strong correlation exists between the size of gestational sac (GS), hCG level and gestational period before sonographic visualization of embryo (Daya S 1987, Nyberg et al. 1985).

Discriminatory hCG Level and Sonographic Correlation (Table 1)

The following thumb rule exists regarding the identification of important landmarks:
- Biochemical pregnancy is established almost immediately after nidation at 5 mIU/mL of β-hCG level on 22nd–23rd postmenstrual day of a regular 28 days cycle.
- On day 26–28, urinary pregnancy test becomes positive (detection limit at 25–50 mIU/mL).
- A tiny 2–3 mm GS can be discerned in a thick shining echogenic endometrium by TV probe on day 32–33 at 1,000–1,500 mIU/mL of β-hCG level (discriminatory level).

Kadar and his associates (1981) enunciated the vital principle that whatever ultrasonography (USG) equipment is used, there is a serum β-hCG value above which GS is always visible, a level below which GS is never detectable; an uncertain zone exists in between. This concept of “discriminatory level” is a path-breaking third epoch making step, forming the basis for a host of diagnostic algorithms.

A paired serum β-hCG samples taken at least 48 hours apart may indicate fall, flattening or a rising trend of hormone concentration. If the increase is less than 66% over 48 hours (equivalent to doubling time of 2.7 days), EP is indicated and laparoscopy is recommended for confirmation (Kadar et al. 1988).
What Happens in Ectopic Pregnancy?

Ectopic pregnancy (EP), like a failed IUP causes impaired β-hCG production in comparison to normal pregnancy, displaying longer doubling time which produces a slow rise or attains a low plateau or slow decline as shown in Figure 1. Serial β-hCG measurement therefore, is mandatory than a single value and offers four types of pictures rendering different prognostic values.

Prognostic Evaluation of Serial β-hCG Assay

Serial β-hCG assay offer four different possibilities:
1. β-hCG above discriminatory zone with empty uterus always suggests EP. On the other hand, the presence of intrauterine GS virtually excludes the possibility of extrauterine pregnancy by extension. Heterotopic pregnancy is extremely rare in spontaneous conception (1:30,000) (DeVoe et al. 1948). We should remember that EPs are more (1 in 10,000 to 1 in 15,000 pregnancies) associated with concomitant IUPs in subjects undergoing artificial reproductive techniques (Richards et al. 1982, Gambardella et al. 1989).
2. β-hCG below the discriminatory zone limits the diagnostic capability of TVS since intrauterine GS won’t be evident. They are low risk patients but can enter high-risk zone with rising hormone level, thus they demand serial scans correlating with serum hormone level.
3. Subnormal rise indicates degenerating trophoblasts likely to resolve spontaneously.
4. Rapidly growing β-hCG level signals danger and suggests functionally active trophoblasts likely to grow further and rupture vide Figure 1.

Pelvic Scan by Transvaginal Sonography and Transabdominal Sonography (Figs 2 to 7)

The accuracy of high resolution-high frequency TV probes over TAS in the early diagnosis of EP has been well documented (Nyberg et al. 1987, Rempen A 1988, Timor et al. 1989, Das et al. 1993).

Transvaginal sonography offers two types of findings:
1. Specific findings: Discern GS, cardiac flicker, yolk sac and other embryonic structures displaying tubal outline.
2. Nonspecific: Like empty uterus, complex adnexal mass and fluid in postoperative day (POD). A high resolution TV probe with its close proximity to the target organ offers an amazingly sharp clear picture not only to characterize the indirect findings better, but displays the tubal outline, identifies the direct findings in about 87% cases (Rottem et al. 1991; Das et al. 1995, Das et al. 2000).
Fig. 2: Day 1: Empty uterus with discrete extrauterine gestational sac display tubal outline.

Fig. 3: Day 1: Note corpus luteum with distinct gestational sac containing yolk sac.

Fig. 4: Day 1: Extrauterine gestational sac displaying increased color mapping and typical low impedance high flow trophoblastic blood flow RI = 0.466.

Fig. 5: Day 1: Left ovary shows corpus luteum blood flow separate from gestational sac.

Fig. 6: Scan on 3rd day after two doses of intramuscular methotrexate 50 mg.

Fig. 7: Day 7: Uterine cavity displaying shedding off endometrium and blood and wrinkled gestational sac.
A living extrauterine embryo is always associated with higher level of hCG. Less specific finding like adnexal mass or intraperitoneal bleeding, however, may occur at any hormone level. The mass is often due to edema, blood clots, necrotic tissue, rather than trophoblasts. Cacciatore and coworkers (1990) diagnosed EP with adnexal mass combined with a serum $\beta$-hCG level at 1,000 mIU/mL (IRP) or above with a sensitivity of 97%, specificity of 99%. It will be pertinent to note here that with the growing refinement of technology, TVS can now identify EPs about 1 week earlier at a much lower hormone level vis-à-vis TAS at 6,500 mIU/mL (Kadar et al. 1981).

**Transvaginal Color Doppler Sonography**

The recent introduction of transvaginal color Doppler sonography (TVCD) added yet another tool to display the increased vascular areas randomly dispersed in the adnexal complex mass and assess the trophoblastic activities, which correlate well with the $\beta$-hCG titer (Kurjak et al. 1994). The test prognosticates trophoblastic invasiveness and can differentiate an active trophoblast from nonviable IUP and pseudogestational sac (Das et al. 2001).

**Uterine Curettage**

Failed intrauterine or molar pregnancy may offer indeterminate sonography findings (doubtful nonviable IUPs).

Chorionic villi can be detected simply by floating uterine curettage in normal saline. A simple bedside “saline test” offers valuable information. The left out placental tissue obtained by suction aspiration floats whereas endometrial tissue sinks in the normal saline. Histopathology report after a couple of days confirms the saline test (Das et al. 1995).

### CURRENT THERAPEUTIC APPROACH

The therapeutic approach over the last decade has gone through four distinct phases: Radical salpingectomy® Conservative tubal surgery® Expectant management® Medical treatment (Table 2).

**Surgical Treatment**

Once diagnosed early, salpingostomy or microsurgery through laparoscopy or laparotomy are common to salvage the tube. Laparoscopic approach to surgical management has been developed and described with increasing frequency and improved outcome. Laparotomy is indicated in hemodynamic unstable condition due to massive hemorrhage or extensive intra-abdominal adhesion. After conservative surgery, however, the risk of persistent trophoblastic disease remains in about 5–10% cases (Lundorff et al. 1991) (Table 3).

The author (BK Mitra and KK Das) has observed that a prior single dose intramuscular methotrexate (IM MTX) carried out

<table>

</tr>
</thead>
<tbody>
<tr>
<td><strong>Steps</strong></td>
</tr>
</tbody>
</table>
| 1. | If semi-quantitative urinary pregnancy test is positive with a lower detection limit at 25 mIU/mL (Pregnancy test, early icon, velocity, etc.) | Pregnancy located unequivocally within the uterus | • Practically excludes EP  
• Still look for the adnexal region to exclude concomitant EP (1:30,000) |
| | | Tubal gestational sac displays embryonic structures like cardiac flicker, yolk sac, etc. | • Unequivocally suggest EP → high risk and is likely to rupture  
• May be false positive pregnancy test  
• May be too early to discern the pregnancy be it IUP or ectopic |
| | Serum $\beta$-hCG below discriminatory level (<1,000–1,500 mIU/mL) | Pelvis entirely normal and no visible adnexal mass | Paired sampling (48 hours apart) to note the $\beta$-hCG trend and prognosis |
| 3. | Serum $\beta$-hCG above discriminatory level (>1,000–1,500 mIU/mL) | Complex adnexal mass with or without fluid in the POD/no IU gestational sac and poorly defined | Needs serial scan correlated with hCG titer medical treatment or laparoscopy/ laparotomy |
| 4. | If serum $\beta$-hCG level falling and → | Intrauterine findings nondiagnostic | Failed IUP?  
Pseudogestational sac? Endometrial aspiration → bedside saline test → HP examination to identify placental tissue |
| 5. | If post D and C shows rising serum $\beta$-hCG and → | Intrauterine findings nondiagnostic | • Indicates active EP  
• Medical/surgical treatment suggested |
Table 3: Four golden rules for nonlaparoscopic presumptive diagnosis of EP

1. Demonstrable tubal GS with embryonic structures
2. Empty uterus above discriminatory zone (1000–1500 mIU/mL IRP)
3. Uterine curettage and saline test in indeterminate TVS → no chorionic villi
4. hCG titer continues to rise after D and C

2–5 days before laparoscopic surgery, makes the procedure easier to perform, induces less bleeding and oozing from the gestational bed. This procedure practically eliminates the risk of persistent EP. The fertility outcome following conservative surgery (78.9%) compares well with that of medical treatment (80.7%) (Debby et al. 2000) and corroborates our experience.

Surgically-administered Medical Treatment

Several chemotherapeutic agents have been used directly in EP using endoscopes, radiological or echo-guided techniques to arrest tubal damage without the risk of systemic side effects. Commonly used drugs for salpingocentesis are methotrexate, potassium chloride, prostaglandins, hyperosmolar glucose or mifepristone. The patient must be hemodynamically stable, tubal diameter should be less than 4 cm, and initial hCG level below 15,000 mIU/mL (Bhatt and Taylor, 1997).

Expectant Management

About 20–30% of tubal pregnancies, resolve spontaneously; if these subjects are identified expectant management become the treatment of choice (Ylostalo et al. 1993).

Criteria for expectant management:
- Falling level of serum hCG at 2 days interval,
- No sign of IUP,
- A diameter of EP less than 4 cm, and
- No signs of rupture or active bleeding by TVS.

Patient selected for expectant management must be closely monitored until spontaneous resolution is complete. Tubal pregnancies have been known to rupture even when the serum β-hCG levels are low (Tulandi et al. 1991). The slow resolution, prolonged follow-up and the need for frequent monitoring, coupled with uncertainty, limits the usefulness and cost effectiveness of this technique (Das et al. 1997).

Medical Management

Methotrexate, an anti-folic acid metabolite, has been successfully used in the treatment of gestational trophoblastic diseases for last four decades. Tanaka and his colleagues in 1982 first used this agent systemically in the treatment of interstitial pregnancy. Since then, MTX has been the most commonly used drug administered intravenously, intramuscularly or orally employing different regimens with folinic acid rescue claiming a success rate of around 60–70% (Goldenberg et al. 1993) (Figs 8 to 11).
Single dose MTX IM (1 mg/kg of body weight) proves to be quite useful in majority of selected cases in ambulatory patients (Stovell et al. 1993). Medical treatment with MTX has many advantages—is effective, less costly, simple, and preferable to surgery and thus more acceptable to the patient (Das et al. 2001). However, key to the success of expectant or medical treatment is our ability to diagnose EP presumptively without the aid of laparoscopy. Once laparoscopy is required to confirm diagnosis, medical treatment becomes less attractive (Das et al. 1997).

The above guidelines depend heavily on the availability of two important resources:
1. Presence of a reliable hormone laboratory
2. The service of an accomplished endovaginal sonographer.

For a developing country with limited resources, a semiquantitative pregnancy kit, close monitoring with pelvic scan and an increased awareness can detect more number of EPs early which may go a long way to salvage tubal potentiality. This is particularly important until in vitro fertilization is more available and affordable with increased success rates (vide a case report given below).

The clinician may adopt variable algorithms. If an early hormone report is not available, a paired sample 5–7 days apart may be helpful, provided the patient’s condition remains stable. The first author (KK Das) observed how amazingly the symptoms settle down within 2–3 days after single dose of MTX therapy in majority of the cases. Post MTX abdominal cramps on day 2–3 is a common finding but alone without hemoperitoneum is not an indication for surgical intervention. However, very rarely one may find the POD fluid (hemoperitoneum) continues to increase with deteriorating general condition, surgery should be performed. It is needless to emphasize that the clinician must motivate the patient, offer proper counseling so that she understands the possible risks involved. Clinician must obtain her informed consent and ensure access to 24 hours emergency treatment.

Serum Progesterone

To avoid the hassles of prolonged TVS and serial hCG measurement, assessment of circulatory progesterone is a second choice to differentiate normal from abnormal pregnancy, takes only 2–3 hours. (Hahlin et al. 1991, Buck et al. 1988, Stovall et al. 1989). A single value of 25 ng/mL or more exclude EP in 95.5% of clinically suspected cases. A concentration of 5 ng/mL is almost 100% correlated with abnormal or nonviable pregnancy. However, there is no cut off value between normal IUP and EP. Concentrations between 10 ng/mL and 20 ng/mL are common and have little differential value.

WHAT FUTURE HOLDS?

- Effective vaccination against *Chlamydia trachomatis*. Once clinically available, it should have a dramatic impact on the frequency of EP and overall health of the female reproductive system (Sepilian V).
- “No other pelvic condition gives rise to more diagnostic errors” as such we are desperately in search of a “specific ectopic markers” (Stabile et al. 1990).
- In another area, attempts are being made to relocate successfully an EP to the uterine cavity: is it a dream or reality? (Wallace CJ 1917, Shettles LB 1990, Pearce et al. 1994, Grudzinskazs JG, et al. 1994).

CONCLUSION

In the recent years, significant improvement has taken place in the understanding of pathophysiology and management of EP. Early diagnosis is possible and we are now embarking in a new era, which promises to remove most EPs from the hands of gynecological surgeons. If medical treatment proves successful in ambulatory patients, laparoscopic diagnosis and surgical treatment (except in rare instances) will become the thing of the past.

ACKNOWLEDGMENTS

We duly acknowledge the help from Dr KC Samanta and Anjan without which this manuscript would not have been possible.

CASE STUDY

Mrs Salimunnisha, 26 years, (Reg. No. 1775) P0 + 1, referred to us on June 15, 2000 for possible conservative treatment suspecting a repeat “ectopic pregnancy”. An infertile subject she was provisionally diagnosed without laparoscopic aid. Earlier she had open salpingo-ophrectomy for tubal rupture and life-threatening hemorrhage 1 year back. The serial images below display how she was managed successfully with two doses of MTX IM and monitoring serum $\beta$-hCG concentration under sonographic guidance (Figs 2 to 11).
BIBLIOGRAPHY

INTRODUCTION

Endometriosis is a chronic, recurring disease, often associated with infertility. It is defined as the presence of endometrial-like tissue outside the uterus, which induces a chronic, inflammatory reaction. It can affect women at any stage in their lives, but is most common in the reproductive years from all ethnic and social groups. Despite high incidence figures, the causes of endometriosis are still open to debate. In addition to uncertainty over pathogenesis of the disease, endometriosis is often misdiagnosed leading to delays in treatment, sometimes for several years. This delay may result in disease progression. The associated symptoms in endometriosis can impact on the physical, mental and social well-being of the woman. However, some women may have no symptoms at all.

INCIDENCE

True prevalence of endometriosis is not known owing to a lack of well-defined epidemiologic studies. It is estimated to affect 71% of women with pelvic pain and 84% of women who have infertility as well as pelvic pain. In asymptomatic women, histologically confirmed endometriosis has been reported to occur in 45–50% of patients at the time of laparoscopy for investigation of infertility.

PATHOGENESIS

A complete understanding of endometriosis has defied researchers, but there are various theories regarding its etiology. The theories have been proposed in an attempt to explain the pathophysiology of endometriosis. Unfortunately, no single theory adequately explains the pathogenesis of this disease.

Transplant Theory

The most frequently cited mechanisms in the development of endometriosis are transplantation of exfoliated endometrial cells and coelomic metaplasia. The transplant theory hypothesizes that, during menstruation, endometrium is deposited in ectopic locations via retrograde menstruation or dissemination through the lymphatic or vascular systems. Multiple studies have demonstrated that endometrial cells within the fallopian tube and peritoneal cavity are viable and capable of implantation. In addition, animal and human studies have confirmed that placement of endometrial tissue into ectopic sites results in histologic transformation into endometriotic lesions; however, transplantation alone does not explain why endometriosis develops in only 5–10% of women when efflux of menstrual fluid has been documented to occur in 76–90%.

Coelomic Metaplasia

The coelomic metaplasia theory cites transformation of the coelomic epithelial lining of the peritoneal cavity, which is composed of differentiated cells capable of dedifferentiating into endometrial-type tissue. Research has not supported that peritoneal cells can undergo transformation, and most metaplastic processes in humans increase with advancing age, whereas endometriosis is usually found in women of reproductive age. The mechanism of coelomic metaplasia may explain the occurrence of endometriosis in women with Müllerian agenesis, postmenopausal women, and women who have undergone hysterectomy.

Genetic Predisposition

The association between genetic predisposition and endometriosis has been based on retrospective analysis of
family histories indicating a polygenic and multifactorial inheritance pattern. In probands from affected families, the onset of endometriosis occurs earlier in life, with more severe disease at the time of diagnosis. First-degree female relatives have a 6–9% occurrence rate versus a 1% rate for nonrelated controls.

**Immunology**

Investigators have also found alterations in cell-mediated and humoral immunity in women with endometriosis. Affected patients have been shown to exhibit increased macrophage activation, decreased T-cell and natural killer cell function, and increased levels of autoantibodies. The significance of autoantibodies and dysfunction of the immune system are controversial and unclear.

**Environmental Toxins**

An increasing area of interest is the role of environmental toxins, such as dioxin, in inducing endometriosis. Human studies have confirmed elevated dioxin levels in patients with endometriosis versus control patients. Molecular aberrations in steroidogenic enzyme function have been implicated in the development of endometriosis. Endometrial tissue from women with endometriosis expresses aromatase P450, whereas endometrium from women without identifiable endometriosis does not. The presence of aromatase within endometriosis results in higher local production of estrogen necessary to maintain lesions.

Rather than one theory explaining the etiology of endometriosis, it is likely that a multitude of factors contribute to its formation. Retrograde menstruation and transplantation of endometrium into ectopic sites may be necessary in activating metaplastic transformation of the coelomic epithelium. In patients with immune dysfunction, genetic predisposition, or prior environmental toxin exposure, clearance of endometrial tissue may be impaired, allowing implantation and growth of lesions. On transformation into endometriotic lesions, aromatase expression may allow continued growth and spread of endometriosis.

Endometriosis is an estrogen-dependent disease; therefore, factors that reduce estrogen levels (e.g. menstrual disorders, decreased body fat content and smoking) are associated with a reduced risk for developing the condition.

**CLINICAL PRESENTATION**

Endometriosis is associated with a wide variety of clinical symptoms and signs, although many patients are asymptomatic. Symptoms of endometriosis are often confused with conditions such as pelvic inflammatory disease, irritable bowel syndrome or even psychosomatic problems.

The classic triad of dysmenorrhea, dyspareunia and infertility has been described as a characteristic of the disease.
formation causing marked distortion of pelvic anatomy. There is usually no correlation.

**DIAGNOSIS**

The classic diagnosis of endometriosis is made by identifying endometrial glands and stroma in extraterine locations or within the musculature of the uterus, defined as adenomyosis. The pelvic structures most often affected by endometriosis in decreasing order of frequency are the ovaries, the anterior and posterior cul-de-sac, the posterior surface of the broad ligament, the uterosacral ligaments, the fallopian tubes, the sigmoid colon, the appendix and the round ligaments. The cervix, vagina and bladder are less frequently affected. The clinical features of endometriosis are shown in Table 1.

Endometriosis is asymptomatic in many women. Pelvic pain caused by endometriosis falls into three categories:
1. Secondary dysmenorrhea, with pain commencing before the onset of the menstrual cycle
2. Deep dyspareunia that is exaggerated during menstruation
3. Sacral backache, worse during menstruation.

The remaining symptoms classically described in endometriosis, such as pelvic pain and painful defecation were similarly distributed in infertile women with and without endometriosis, whereas dyspareunia even showed a trend to a protective effect. This fact could be the result of an increased prevalence of the aforementioned symptoms in infertile women or to a different behavior of endometriosis associated with infertility in regard to the other varieties of endometriosis. The presence or absence of dysmenorrhea or of the remaining clinical symptoms in an infertile woman is of no value to suspect or discount endometriosis.

A number of the findings classically described as suggestive of endometriosis are as follows:
- Painful cervical mobilization
- Uterine lateralization and limitation of uterine mobility
- Painful ovarian palpation
- Adnexitis.

But these clinical features are also present in women with and without endometriosis. There is a higher frequency of uterine retroversion and nodularity in the pouch of Douglas in endometriosis cases. The presence of a fixed uterus in the pelvic examination is often seen in endometriosis. Uterosacral nodularity and uterosacral tenderness are the only findings that are significantly increased in endometriosis cases. Their frequencies are much higher than in infertile women without endometriosis (odds ratio > 11.7 and odds ratio = 4.6). The association between severity of endometriosis and severity of symptoms is controversial. Many of the differences can be attributed to the different methodologies and populations studied.

The predictive value of any one symptom or set of symptoms is uncertain, as a significant proportion of affected women are asymptomatic. Establishing the diagnosis of endometriosis on the basis of symptoms alone can be difficult because the presentation is so variable.

Definitive diagnosis of endometriosis depends on visual inspection of the pelvis at laparoscopy (Figs 2A and B). It is good to use an instrument such as a grasper, via a secondary port, to mobilize the pelvic organs and to palpate lesions, which can help determine their nodularity. It is also important to document in detail the type, location and extent of all lesions and adhesions. It is unnecessary to obtain a positive histological diagnosis, visual inspection is usually adequate.

When compared with laparoscopy, transvaginal ultrasound has limited value in diagnosing peritoneal endometriosis but it is a useful tool both to make and to exclude the diagnosis of an ovarian endometrioma.

**MANAGEMENT (FLOW CHART 1)**

The treatment of women with endometriosis can be a challenge. Therapeutic strategies must be tailored to the individual symptoms, age, and desire for fertility. Endometriosis can be managed effectively with medical therapy, surgery or a combination of both. Therapy is directed toward the severity of symptoms, the extent of disease, the location of disease and desire for fertility.
Endometriosis

Flow chart 1: Management of endometriosis

MEDICAL MANAGEMENT (TABLE 2)

The observation that endometriosis is rarely seen in hypoestrogenic postmenopausal women, led to the concept of treating the disease by inducing a pseudomenopausal state. Treatment is directed toward the estrogen responsiveness of endometriosis, thus the goal of therapy is to induce either a pseudopregnancy (oral contraceptives, progestin) or a menopausal state [gonadotropin-releasing hormone (GnRH) analog] to inhibit or delay progression.
The role of medical therapy in the treatment of women with endometriosis has changed dramatically. In the 1980s, the development of GnRH agonist created a breakthrough in the management of endometriosis.

These approaches are supported by spontaneous regression of endometriosis and associated symptoms during menopause in most patients secondary to a decrease in estrogen production. Medical therapy continues to be based on endocrine treatment such as oral contraceptives, progestins, danazol and GnRH agonists.

Unfortunately, recurrence rates are high after discontinuation of therapy. Recent clinical research on GnRH analogs plus add-back therapy has produced favorable results. Long-term treatment of patients using this approach has successfully reduced pain while minimizing symptoms of hypoestrogenism and adverse metabolic effects such as loss of bone mineral density (BMD). Currently, GnRH analogs given with add-back therapy seems to be the most effective long-term approach to the treatment of symptomatic endometriosis. In the future, other modalities, such as medicated vaginal rings, inhibitors of steroidogenic enzymes and GnRH antagonists, will be the most likely options.

**Oral Contraceptives**

The initial management of the patient suspected of having endometriosis based on history and physical examination who does not currently desire fertility may be treated with oral contraceptives. But endometriosis can remain active despite oral contraceptives, and some patients will continue to complain of symptoms. If the patient fails to experience relief of symptoms within 3 months of initiating oral contraceptive therapy, a more aggressive medical modality is warranted. No evidence supports switching from one oral contraceptive formulation to another in an attempt to improve response.

**Progestins**

Progestins are frequently used in the management of endometriosis. Progestational agents inhibit endometriotic tissue growth by causing an initial decidualization and eventual pseudonecrosis or atrophy. Progestins oppose the growth-promoting effects of estrogen by altering clearance of the nuclear estrogen receptor and inducing 17 beta-hydroxysteroid dehydrogenase, which converts estradiol to estrone. At high doses, progestins will also inhibit gonadotropin secretion and ovarian hormone production, inducing an amenorrheic state.

Associated side effects include weight gain, fluid retention, headaches and depression. All of these effects resolve after discontinuation of therapy. Oral administration of medroxyprogesterone acetate, 50 mg daily, improves symptoms in 80% of patients with moderate to severe endometriosis. Unfortunately, recurrence rates have been reported to reach 42% after 2 years of therapy. As an alternative to medroxyprogesterone acetate, one may choose to administer norethindrone acetate, 5 mg daily for 6 months. A similar response can also be achieved with 40 mg of megestrol acetate daily. Parenteral medroxyprogesterone acetate depot may also be given at a dose of 100 mg every 2 weeks for 3 months followed by 200 mg monthly for 3–6 months.

**Danazol**

Danazol, a synthetic derivative of 17 alpha-ethinyltestosterone, was introduced into clinical practice in 1971. Danazol directly inhibits steroidogenic enzymes, endometriotic implant growth and pituitary gonadotropin secretion, and interacts with androgen and progesterone receptors. Sex hormone-binding globulin (SHBG) levels are also reduced, resulting in elevated free testosterone levels, which promote androgenic side effects such as acne and hirsutism. Danazol produces a hypoestrogenic-hyperandrogenic environment that is unfavorable for the growth of endometriotic lesions.

Other side effects of danazol include weight gain, hot flushes, mood changes, depression, muscle cramps, decreased breast size, decreased high-density lipoprotein (HDL) levels and increased liver enzymes.

More than 80% of patients experience relief or improvement of pain symptoms within 2 months of starting treatment with danazol. Danazol has been shown to reduce pain better than placebo for up to 6 months after discontinuation of therapy. Unfortunately, the recurrence of symptoms within 4–12 months of discontinuation of therapy approaches 50% in most studies.

Danazol is given orally in divided doses ranging from 400 mg to 800 mg daily for 6 months. A 6-year prospective study evaluating the effectiveness of danazol at 400 mg and 800 mg found no difference in side effects between the two doses, and gross resolution of the disease was similar.

A recent study investigated the use of a vaginal danazol ring for the treatment of endometriosis. Eighty-eight percent of participants with deep endometriosis had a decrease in dysmenorrhea, and 92% had a decrease in tenderness of the cul-de-sac within 3 months. Preliminary data suggest that danazol rings are effective in treating severe endometriosis while avoiding androgenic side effects.

Trials evaluating the effect of danazol on fertility in comparison with expectant management have shown no increase in pregnancy rates. Concerns have been expressed...
regarding the androgenic action of danazol and potential harm to a developing female fetus. Despite anovulation owing to decreased gonadotropin secretion, patients are encouraged to use barrier contraception.

**Gonadotropin-releasing Hormone Agonists**

The most predictable form of medical therapy that inhibits estrogen production by the ovaries is GnRH agonist. Continued exposure to GnRH leads to a hypogonadal state with decreased release and suppression of estradiol from the ovaries. GnRH agonists bind to receptors in the pituitary gland, initially resulting in a release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), followed by modulation, a decrease in gonadotropin secretion, and, eventually, cessation of estrogen production by the ovaries. In a hypoestrogenic environment, endometriosis will undergo quiescence and atrophy with improvement in symptoms.

Gonadotropin-releasing hormone may also be used as a diagnostic test to determine whether pelvic pain is estrogen-related, in patients who continue to suffer pain when laparoscopy is unrevealing. The decrease in mean serum estradiol concentration was also more significant with GnRH analog than with danazol.27

Gonadotropin-releasing hormone therapy is also associated with a recurrence of symptoms, as is true for other medical modalities. Dysmenorrhea returns in 57% of patients within 6 months of discontinuation of therapy. Histologically proven relapse has been observed in 13.3–15.6% of women after GnRH analog therapy. Patients with severe forms of endometriosis are more likely to have recurrence of pain, with an overall recurrence rate of 43.8%.

Gonadotropin-releasing hormone agonist formulations are available as nasal sprays or injection. The usual dose is 400–800 µg daily for nasal nafarelin, 3.6 mg for monthly subcutaneous goserelin and 3.75 mg for monthly intramuscular leuprolide.

Gonadotropin-releasing hormone agonists do not have androgenic or progestogenic side effects or negative impact on lipid profile; however, the side effects associated with a hypoestrogenic state may be severe. These effects include vaginal dryness, hot flushes, insomnia, depression, libido changes, headache and fatigue. A decrease in trabecular bone density of up to 6% in 6 months has been reported. This effect is largely reversible after discontinuation of therapy but limits the time this agent can be used. The long-term effect of multiple courses of GnRH analog therapy in young women is unknown, and there is potential for delayed adverse effects on BMD.

The addition of add-back therapy to GnRH analog treatment has gained wide acceptance and minimizes the hypoestrogenic side effects of the analog while preserving therapeutic efficacy. The ultimate goal is to decrease vasomotor symptoms and detrimental effects on bone density to enhance compliance with prolonged duration of therapy. The addition of progestin alone was first employed as add-back therapy.28 Vasomotor symptoms and bone density loss could be reduced with a 100 mg daily add-back of medroxyprogesterone acetate but apparently not with lower doses. Several studies have shown that transdermal 17 beta-estradiol or conjugated equine estrogens administered with medroxyprogesterone acetate result in decreased vasomotor symptoms and decreased bone loss without increasing pain. The addition of bisphosphonates to norethindrone also eliminates BMD loss; however, in light of the cost of bisphosphonates and concerns over long-term effects in young women who desire future fertility, further studies are indicated before this adjunct can be used as a standard approach. Unfortunately, after discontinuation of GnRH agonist and add-back therapy, recurrence rates are similar to the rates reported for other medical therapies.

Repeat therapy or extended periods of treatment with GnRH agonists has previously been limited due to their effects on BMD. However, the loss of BMD does show a gradual return toward baseline following treatment discontinuation. By giving add-back using an estrogen/progestogen preparation with a GnRH agonist:

- The impact of treatment on BMD loss is reduced
- Vasomotor symptoms such as hot flushes are relieved
- Efficacy of treatment on endometriosis symptoms is unaffected.

**Aromatase Inhibitors as a Treatment for Endometriosis**

Recently aromatase inhibitors are prescribed for women with endometriosis who have not had success with other treatments or who cannot use other treatments because of their side effects. At this moment, the treatment of endometriosis with aromatase inhibitors is still in the research stage.

Aromatase is a protein in the body that is responsible for producing estrogen. Normally, it is found in the ovaries, and to a much lesser extent in the skin and fat. Research has shown that aromatase is also found in high levels in the ectopic endometrial tissue of women with endometriosis, which contributes to their growth. Aromatase inhibitor suppresses the growth of endometriosis and reduces the associated inflammation. This, in turn, significantly reduces their pelvic pain.30–33

It has been established that medical treatment does not improve the chance of pregnancy for subfertile women with endometriosis. It has also been established that medical treatment of endometriosis-associated pain is effective, although little or no difference exists among the various medical treatment modalities available: continuous combined oral contraceptives, danazol, gestrinone, androgens, progesterone derivatives and GnRH analogs. Many have considered the beneficial effect on pain to correlate with a therapeutic effect on subfertility. However, a causal relationship between endometriosis and subfertility remains to be established.
Mirena as a Treatment for Endometriosis

The Mirena is increasingly being used to treat women with endometriosis. It contains levonorgestrel that is released into the uterus over a period of 5 years. Only a few studies have been published, the studies indicate that it is an effective treatment for endometriosis, and may have the potential to be a long-term treatment for women who want to postpone pregnancy. It offers several potential advantages over other current treatments.

Most common side effect of Mirena is irregular vaginal bleeding, frequent spotting or light bleeding between periods. However, these problems usually settle after 3–6 months.

SURGICAL TREATMENT (TABLE 3)

Surgical treatment is no longer the first-line therapy. Surgery is indicated in patients who have failed medical therapy and who have physical findings of extensive endometriosis such as endometriomas. Ovarian cystectomy, oophorectomy, hysterectomy and total hysterectomy are radical options, which, while often curative but are unsuitable for women wishing to retain fertility.

Treating early stage endometriosis to improve fertility is still controversial. Some studies have suggested that laparoscopic surgery is effective in increasing the incidence of pregnancy. In patients with significant physical findings or symptoms, the threshold for laparoscopy should be lower.

Total abdominal hysterectomy and bilateral salpingo-oophorectomy remain a definitive cure for symptomatic endometriosis but only possible in patients who have completed their families. In extensive endometriosis, surgical intervention requires extreme care and is best attempted by experienced and skilled surgeons. Following radical surgery involving oophorectomy, patients often require hormone replacement therapy.

Laparoscopic Excision

Over the last decade, laparoscopic surgery is gradually getting wider acceptance in the surgical management of endometriosis. The advantages of the laparoscopic approach are obvious. The aim is complete ablation or excision of the active endometriotic tissue and correction of anatomical distortion induced by the adhesions and cystic ovarian lesions and this should be achieved with minimum damage to the healthy tissue.

The most effective laparoscopic technique, excision, coagulation or vaporization is still being debated but it does not appear to be crucial for the eventual outcome. As endometriosis is an invasive disease and occasionally infiltrates deeply in the surrounding structures, ablation is as dangerous as excision. One should be able to identify the disease and to use the most effective surgical modality for each location and each patient. The following modalities are generally used:

- **Adhesiolysis**: This is the most important step in endometriosis.
- **Excision**: The lesions are identified and carefully excised usually after prior coagulation.
- **Vaporization**: The CO₂ laser is the best instrument to vaporize peritoneal implants.
- **Coagulation**: Occurs with lower energies as in a bipolar cautery and results in lower temperature at the tissue levels.

Laparoscopic surgery can be used to excise endometriosis from any pelvic location. Resections of uterosacral ligaments, excision of endometriomas, bowel lesions and ovaries or tubes are possible through the endoscopy. Excision techniques and procedures are the standard surgical techniques used at laparotomy. Very dense or widespread adhesions or some bowel lesions may require laparotomy in some patients.

Endometrioma

Endometriomas most frequently occur in the ovary and may present as an asymptomatic pelvic/abdominal mass.

Several surgical treatments are available for endometriomas:

- **Simple puncture**: This procedure is completed by draining the chocolate colored fluid from the cyst. Endometriomas have been shown to recur in about 50% of the patients treated with simple puncture, hence a more aggressive surgical approach is now recommended.
- **Ablation**: Another approach is to drain the cyst and remove its base with laser or electrosurgery.
- **Excision of the cyst wall**: This is the procedure of choice to decrease recurrence of disease. Endometriomas may recur in 8% of the patients treated with this procedure. Results from several different prospective studies have reported pregnancy rates of 50% over 3 years. There are no randomized clinical trials comparing these different treatment methods.

ENDOMETRIOSIS AND CANCER RISK

Women with endometriosis have a mildly increased risk for development of epithelial types of cancer of the ovary. This
risk seems to be highest in women with endometriosis and primary infertility, but the use of oral contraceptive pills, which are sometimes used in the treatment of endometriosis, appears to significantly reduce this risk.

The reasons for the association between endometriosis and ovarian epithelial cancer are not clearly understood. One theory is that the endometriosis implants themselves undergo transformation to cancer. Another possibility is that the presence of endometriosis may be related to other genetic or environmental factors that also increase women’s risk of developing ovarian cancer.

**ASSISTED REPRODUCTION IN ENDOMETRIOSIS**

Patients diagnosed as suffering from endometriosis should be referred for assisted reproduction early. The results are encouraging in a younger couple seeking advice early in the course of their treatment. Intrauterine insemination (IUI) improves fertility in minimal-mild endometriosis: IUI with ovarian stimulation is more effective. In vitro fertilization (IVF) is appropriate treatment especially if tubal function is compromised, if there is also male factor infertility, and/or other treatments have failed.

Laparoscopic ovarian cystectomy is recommended if an ovarian endometrioma greater than or equal to 4 cm in diameter is present to confirm the diagnosis histologically; reduce the risk of infection; improve access to follicles and possibly improve ovarian response. The woman should, however, be counseled regarding the risks of reduced ovarian function after surgery.

**CONCLUSION**

The enigma that is endometriosis requires decision making at every stage by physician and patient alike. The complexities surrounding diagnosis, when to treat, sequence and combinations of treatment all add up to a truly mysterious disease.

Current evidence suggests that pain caused by endometriosis can be mostly managed medically. Progestins, danazol, oral contraceptives, nonsteroidal anti-inflammatory drugs and GnRH agonists have all been shown to reduce the size of lesions. However, no medical therapy has been proved to eradicate the lesions.

Surgery for women with endometrial pain is associated with significant reduction in pain during the first 6 months following surgery. However, up to 40% of women experience a recurrence of symptoms within 1 year.

The following recommendations from the American College of Obstetricians and Gynecologists (ACOG) are based on Level A (good and consistent) scientific evidence:

- For pain relief, treatment with a GnRH agonist for at least 3 months or with danazol for at least 6 months appears to be equally effective in most women.
- When relief of pain from treatment with a GnRH agonist supports continued therapy, the addition of add-back therapy reduces or eliminates GnRH-induced bone mineral loss without reducing the efficacy of pain relief.
- Therapy with a GnRH agonist is an appropriate approach for the management of the woman with chronic pelvic pain, even in the absence of surgical confirmation of endometriosis, provided that a detailed initial evaluation fails to demonstrate some other cause of pelvic pain.
- For pain relief, oral contraceptives and oral or depot medroxyprogesterone acetate are effective and may be equivalent to other more costly regimens.
- Hormone replacement therapy with estrogen is not contraindicated following hysterectomy and bilateral salpingo-oophorectomy for endometriosis.
- For severe endometriosis, medical treatment alone may not be sufficient.

Because endometriosis often is unpredictable and may regress, expectant management may be appropriate in asymptomatic patients.

So long as we do not understand the exact pathogenesis of endometriosis, rational treatment will remain elusive. Also, the natural course of the disease is enigmatic: Why does endometriosis not progress beyond the minimal/mild stage in most women? Why, when and how does it resolve spontaneously with time, if at all? Why, when and how does it cause pain (dysmenorrhea, dyspareunia, chronic pelvic pain)? Endometriosis is a disease that waxes and wanes. Until we understand what makes endometriosis start and why it stops again spontaneously after some time, we will not be able to understand the disease or devise a permanent cure.

**REFERENCES**

INTRODUCTION

Urinary tract infections (UTIs) are common in women. Usually UTIs are benign and easily treated. But recurrent and persistent infections can lead to serious disease. The incidence of UTI is 1% among school children (aged 5–14 years), increases to about 4% by young adulthood and by an additional 1–2% per decade of age. In addition, the older a woman, the more likely she is to have a reinfection. UTIs are important because 20% of women aged 20–65 years suffer one attack per year and approximately 80% of women develop a UTI during their lives. The probability of recurrent UTIs increases with the number of previous infections and decreases in inverse proportion to the time elapsed between the first and second infections. Of these recurrent infections, 71–73% are caused by reinfection with different organisms, rather than recurrence with the same organism. UTIs account for more than 40% of all nosocomial infections. 12–25% cases of chronic renal failure are attributed to chronic pyelonephritis. UTIs can be hazardous when associated with an abnormal urinary tract, in pregnancy or in the presence of underlying diseases such as diabetes and hypertension. Acute symptomatic urinary infections are common in women between 20 years and 50 years of age while asymptomatic bacteriuria (ASB) is more common in elderly women.

TERMINOLOGY

The term bacteriuria is used to define the presence of living bacteria in freshly voided urine or urine obtained via suprapubic aspiration. Although 50% of women with lower UTI have 100,000 or more organisms per milliliter cultured from urine, approximately one-third of women who present with symptoms of acute dysuria, frequency and urgency have between 100 and 100,000 organisms per milliliter by properly obtained culture, and yet warrant a diagnosis of UTI. Studies of bladder urine specimens obtained by suprapubic aspiration or by transurethral catheterization demonstrated that smaller number of organisms in symptomatic women is associated with bacteriuria, pyuria and a predictable response to UTI therapy. The concept of significant bacteriuria or a single organism colony count of 100,000 or more organisms per milliliter is appropriate when applied to ASB or acute pyelonephritis. In 1956, Kass proposed that the isolation of more than 100,000 colony forming units (cfu) or organisms per milliliter of midstream voided urine should be used to differentiate probable contamination from ASB.

Asymptomatic bacteriuria is the term used to describe the condition in which there is significant bacteriuria although the patient remains asymptomatic. It is found in approximately 5% of young women and increases with age, reaching a prevalence of 22–43% in elderly women. In general it is not thought to be of clinical significance, except in certain clinical circumstances such as pregnancy, instrumentation of the lower urinary tract and renal transplant patients. It is more likely to be present in those patients with a chronic indwelling catheter.

Recurrent UTI is the term used to describe a symptomatic infection that follows the resolution of a previous UTI, generally after treatment. It occurs in 12–27% of women after their first UTI and in 48% of women who have had a previous UTI. The ratio of recurrent UTI to pyelonephritis has been estimated to range between 18:1 and 28:1.

Recurrent infection may be due to relapse of the original organism or to reinfection with the same or a different organism. As it is often difficult to differentiate between
relapse and reinfection, a relapse is defined as a recurrent UTI caused by the same organism, and a reinfection as a recurrent UTI caused by a different organism. Around 80–90% of recurrent infections are due to reinfections, with one-third being with the same organism.

Complicated lower UTIs are infections that may be related to other pathology (Table 1). One of the most common forms of complicated UTI is related to the use of catheterization. The incidence of bacteriuria associated with an indwelling urinary catheter is 3–10% per day, and the duration of catheterization is the most important risk factor for developing infection of the lower urinary tract. Whereas less than 5% of catheter-induced episodes of bacteriuria result in bacteremia, they represent a huge reservoir of resistant bacteria in the hospital environment.

Cystitis indicates inflammation of the bladder but is often used by patients to indicate any UTI. A symptom of dysuria, urgency and frequency unaccompanied by significant bacteriuria has been termed the “acute urethral syndrome” and is sometimes interchangeable with “frequency dysuria syndrome (FDS)”. Acute bacterial pyelonephritis indicates acute infection of the kidneys. The term chronic pyelonephritis indicates chronic inflammation of the renal and tubular tissues, with scarring and shrinkage secondary to interstitial fibrosis. There is accompanying reduction in the glomerular filtration rate and tubular function.

Bacterial Virulence Factors

Uropathogens have the ability to survive and multiply in the bladder, as well as being able to adhere to the bladder epithelium. Adherence of the organism to the bladder wall triggers an acute inflammatory response by the activation of cytokines. These in turn stimulate the production of an intracellular adhesion molecule, which by leukocyte adhesion causes migration of cells to the point of infection. This prevents the organism from being “washed out” and, by increasing their nutrient supply, they divide more efficiently.

The structure of bacteria is also known to be important when considering virulence and pathogenicity. Various bacterial adhesions, surface receptor sites and attachment properties of bacteria have been identified. Pili and fimbriae are found on the outer membrane of some bacteria and promote binding, using an adhesion molecule on their tip. P-fimbriae mediate adherence to the glycolipids in the urothelium whilst type I fimbriae confer the ability to adhere to the mucous layer within the bladder. Enterobacteriaceae have an antigenic structure that induces an antibody immune response. The outer cell membranes contain O antigens, which, together with endotoxins, initiate the immune response in the bladder wall by stimulating cytokine production. Capsular (K) antigens on the surface of the bacteria help to inhibit phagocytosis and immunoglobulin A (IgA) and IgG in the urothelium. Finally some bacteria are able to break down bladder mucin and invade the urothelium beneath.

Host Factors

Flora, particularly coliforms from the gastrointestinal tract colonize the vagina and periurethral area and ascend into the bladder. The female urethra appears prone to colonization with colonic Gram-negative bacilli, owing to its proximity to the anus and its short length (about 4 cm). Natural defenses against the bacterial adherence to and the ascent into the urinary tract include various substances produced by the urinary tract, local immunoglobulins, competitive bacterial flora and normal voiding patterns.

The bladder mucosa is thought to have a bactericidal action and produces a surface layer of mucus, providing an antibacterial barrier. The lamina propria of the bladder wall and urethra has also been shown to synthesize IgA, and this also has a bactericidal effect by preventing bacterial adherence. Finally, Tamm-Horsfall protein, a mucoprotein shed from the renal tubular cells and excreted in the urine, has been shown to bind and trap E. coli and to be increased in patients with pyelonephritis and vesicoureteric reflux. The maintenance of an infection-free urinary tract relies first on regular and complete flushing of the system with a steady flow of urine from the kidneys and secondly the presence of friendly flora in the vagina and vulva. Anatomical abnormalities and neurological diseases may interfere with flushing. The friendly flora is disrupted by sexual activity, particularly when spermicides are used.

Among sexually active women, lower UTIs are associated with sexual intercourse. Urethral massage, as occurs during sexual intercourse causes introduction of bacteria into the bladder and appears to be very important in the pathogenesis of urinary infection in younger women. In recently married, consummation of marriage may traumatize the urethra and bladder base causing dysuria and “honeymoon cystitis”. Large proportions of susceptible women become symptomatic within a short period of time after intercourse. Strom et al. found that sexual intercourse in the previous 48 hours had an odds ratio for UTI of 58.1 and was the single most important factor in the development of UTIs. Use of diaphragm and spermicidal-coated condoms has been linked to an increased incidence of UTIs caused by E. coli. Handley et al. found that the largest risk of UTI was associated with exclusive condom use and use of nonoxynol-9-coated condoms.

Urinary infections are detected in 2–8% of pregnant women. Nearly 5% of women at their first antenatal visit have ASB. 20–30% of women with ASB develop acute pyelonephritis during pregnancy; have lower hemoglobins, which improves with eradication of the ASB and hypertension is more common, especially in association with renal scars. A significant number of patients with ASB have chronic renal disease. There is also a greater risk of prematurity and an increase in perinatal mortality. This predisposition to upper UTI during pregnancy results from the decreased ureteral tone and peristalsis and temporary incompetence of the vesicoureteral valves seen in pregnancy. Bladder catheterization during or after delivery without proper asepsis may cause additional infections. Sickle-cell anemia and sickle-cell trait in pregnant women has been correlated to an increased incidence of UTIs.

Although the symptoms of acute UTI resolve within a few days of starting antibiotics, the epithelium may take weeks to recover completely. During this recovery period its resistance to further infection is impaired and recurrent infection is more likely. Approximately 20% of women with UTIs have recurrences of symptoms within variable periods of time. Recurrences are most often reinfections, demonstrated by culture negativity between episodes and by the isolation of different organisms as shown by determining the biotype and the sensitivity patterns in each episode. Recurrences develop in characteristic clusters of symptomatic UTI, often during 6–12 month time periods.

Less frequently recurrent symptoms result from the persistence of the same organism after therapy is halted and is referred to as relapse. Close intervals of 10–14 days between symptomatic recurrences may indicate upper UTI. Persistence of single organism raises the concern of congenital or acquired structural or functional abnormalities of the urinary tract.
PRESENTATION

Symptoms

Adult women with dysuria, frequency, urgency and suprapubic pain usually have acute cystitis. In some cases, the patient recognizes that sexual intercourse may be the precipitating factor. In acute pyelonephritis, symptoms generally develop rapidly over a few hours or a day and include fever which is often 38°C or greater, with chills, nausea and vomiting. Though loin pain and fever are more common, symptoms of cystitis may coexist.

Patients with recurrent UTIs must be instructed to keep a record of the time of the day and volume every time the woman passes urine. This introduces an objective measurement, which is useful when assessing the severity of her symptoms and monitoring the response to treatment.

Physical Signs

In acute cystitis/urethritis, suprapubic tenderness is often present and palpation in this region may provoke a desire to pass urine. In adult pyelonephritis, the patient looks ill, has tachycardia and fever, which is often greater than 38°C. Physical examination reveals marked tenderness on deep pressure in one or both costovertebral areas. In some signs and symptoms of Gram-negative sepsis predominates and patients may have hypotension accompanying the tachycardia.

DIAGNOSIS

Urine Analysis

Infected urine may look cloudy. Commercial “stick test” is useful to detect glycosuria, proteinuria and hematuria. A positive leukocyte esterase test is 75–95% sensitive and 95% specific in detecting more than 10 WBCs/mL, consistent with a UTI. Some sticks can also reveal the presence of nitrites in the urine, which indicates Gram-negative bacterial infection if positive it has a specificity of greater than 92% for UTI.

Urine Microscopy and Culture

Microscopy of a fresh specimen of urine from a patient with UTI will detect bacteria and pus cells in abundance. The presence of casts indicates renal disease. The presence of pus cells and subsequent failure to isolate a pathogen is called sterile pyuria and alerts the clinician to the possibility of tuberculosis. The majority of women with symptomatic UTI who later are documented to have bacteriuria have pyuria with more than 8–10 WBCs/mL in unspun urine and 2–5 WBCs/HPF in spun urine sediment. The presence of hematuria in the absence of pus cells or bacteria suggests pathologies other than infection, e.g. renal calculi, bladder polyps and carcinoma. A midstream clean voided urine sample obtained after washing the introitus with tap water without soap and water is inoculated on a selective culture medium such as MacConkey within 20 minutes. If delayed, the urine must be refrigerated to 4°C. If lower UTI is associated with bacterial counts between 100 and 100,000 colonies/mL, contamination of specimens with other organisms may confuse the interpretation of culture results. Counts obtained between these two limits should be interpreted considering each specific clinical setting. Urine cultures that reveal 100,000 or more colonies/mL of a single pathogen support the diagnosis of UTI in asymptomatic women whereas cultures that reveal 100 or more colonies/mL of a single pathogen support the diagnosis of UTI in symptomatic women.

A quantitative estimate of the degree of bacteriuria can be made by direct microscopic examination of a Gram’s stain of uncentrifuged, freshly voided urine. If bacteria can be found by this method, it may be assumed that the number present approximates 100,000/mL. Identification and antibiotic sensitivity testing complete the microbiological report.

If there is a significant delay between collecting a sample of urine and platting it on culture medium some clinicians use a dip slide system. A slide coated with solid culture medium is dipped into the urine specimen and then transported to the laboratory in a sealed container. This technique has a false-positive rate of up to 10% and false-negative rate of up to 3%.

Imaging

Imaging studies are useful for detecting congenital anomalies of the urinary tract, obstruction, calculi and vesicoureteral reflux. Indications for imaging studies are children with UTI, adults suspected to have an upper UTI and adults with lower UTIs who fail to respond to treatment, have recurrent episodes of UTI or have symptoms suggesting some urinary tract pathology such as obstruction or calculi.

Ultrasound Examination

It is used to measure the dimensions of the kidney and to detect obstruction of their drainage. It will also reveal residual urine following incomplete bladder emptying. It is a well-tolerated, noninvasive investigation. Transvaginal ultrasound should be performed to exclude the possibility of a pelvic mass.

Plain Abdominal Radiograph

Most calculi and calcification seen in some chronic infections such as tuberculosis can be detected.

Intravenous Urography

Intravenous (IV) urography now has limited application in the investigation of the urinary tract, as relatively high doses
of radiation are a definite disadvantage and has not been shown to influence treatment in majority of the cases. It is usually used to demonstrate precise anatomic relations of the ureter. This may be helpful in planning surgeries involving the ureters.

**Computed Tomography Scan**

It displays cross-sectional anatomy and clearly delineates renal and perirenal pathology. It is particularly helpful in detecting renal and perinephric abscesses, acute focal bacterial nephritis and emphysematous pyelonephritis.

**Cystoscopy**

It is indicated in women with recurrent urinary infections and symptomatic women without significant bacteriuria. Other causes of lower urinary symptoms, such as carcinoma in situ, interstitial cystitis or tuberculosis can be detected and a biopsy undertaken to confirm the diagnosis.

**Approach to Imaging**

The combination of a plain abdominal radiograph and ultrasound has been compared with traditional IV urography in the investigation of patients with UTI. Both have similar sensitivities and concur in 96% of cases. IV urography involves a greater dose of radiation and is more expensive. It is wise to commence with a plain abdominal radiography and ultrasound. In most cases of UTI in adults this will be normal and no further imaging is warranted. If any abnormality is detected other imaging studies may be done.

**Blood Tests**

Plasma creatinine and urea concentrations are important measurements of renal function and should be performed in all cases other than solitary episodes of cystitis in adult women. The fasting plasma glucose concentration and oral glucose tolerance test are superior to tests for glycosuria when considering diabetes mellitus.

### MANAGEMENT

**General Measures**

The management of lower UTI is aimed at treating the current infection and preventing further recurrences. The aims of treatment are as follows:

- Symptomatic relief
- Clinical cure
- Microbiological cure
- Detection of predisposing factors
- Prevention of upper urinary tract involvement
- Management and prevention of recurrence.

The management and prevention of UTIs are closely related. Local hygiene is very important in the success of treatment and prevention of reinfection. Women must be told that perineal toilet should be done by wiping the perineum from the vagina toward the anus so as to avoid fecal contamination of the urethra, especially during an episode of diarrhea. Potentially irritant vaginal deodorants and bubble baths should be avoided and a high standard of perineal hygiene maintained. Patients with recurrent UTI should have plenty of oral fluids. Regular and complete bladder emptying must be taught and the concept of double micturition emphasized to those with residual bladder urine after voiding.

The complaint of postcoital UTI symptoms provides the ideal opportunity to review contraceptive methods. Oral contraceptives must be advised rather than condom if there is much irritation with the latter. The women must be instructed to void as soon as possible after intercourse.

Cranberry juice has also been shown to be an important factor in the prevention of lower UTIs. Regular intake of at least 300 mL/day has been associated with a reduced risk of UTIs. Cranberry juice is thought to act by reducing bacterial adherence to the bladder wall.

**Antimicrobials**

An antimicrobial should be selected that has the appropriate sensitivity and is also able to achieve a high concentration within the urinary tract. Ideally the drugs should be rapidly absorbed and not induce bacterial resistance (Table 3).

**Asymptomatic Bacteriuria**

Pregnant women and women with renal scars from previous infection with ASB need treatment. ASB should be demonstrated with at least two positive cultures before treatment is given. Seven days of an oral agent to which the organism is sensitive should be given initially. If bacteriuria persists, it can be followed without further treatment in most patients. In patients who may be at high-risk because of

...
neutropenia, compromised host defenses, renal transplant or previous development of pyelonephritis or bacteremia, further treatment with either 6 weeks of oral therapy or 4–6 weeks of combined parenteral and oral therapy should be given.

**Acute Uncomplicated Cystitis**

More than 90% of infections are due to *E. coli* and most strains are sensitive to many antibiotics. Amoxicillin, trimethoprim, sulfa or a quinolone may be a good first choice. The latter two should not be used in women at risk for pregnancy or pregnant (Table 4). Cephalosporins have an unacceptably high-risk of precipitating vaginal candidiasis and should be avoided in this setting.

Several studies have proved that single dose of medication is sufficient to treat approximately 80% of uncomplicated lower UTI. Appropriate single-dose agents include amoxicillin (3 g), trimethoprim (400–600 mg), sulfasoxizole (2 g), and trimethoprim-sulfamethoxazole [2 double strengths (DS)]. Cephalosporins are not effective as single-dose agents. Single-dose therapy should not be used in women with symptoms or signs of pyelonephritis or in women with urologic abnormalities or stones. Most practitioners and their patients will find a 3 days course with either trimethoprim, norfloxacin, ciprofloxacin or ofloxacin acceptable.

Treatment of acute urethritis in women depends on the etiological agent involved. In Chlamydial infection, tetracycline (500 mg orally QID for 7 days) or azithromycin (1 g) as a single oral dose should be used.

**Acute Pyelonephritis**

Treatment may require hospitalization, IV antibiotics and hydration. A 10–14 days course of trimethoprim-sulfamethoxazole, trimethoprim alone, an aminoglycoside, third generation cefephalosporin, augmentin or ciprofloxacin usually provides adequate therapy. Antibiotics must be given intravenously and should be continued for at least 24 hours of a febrility followed by oral antibiotics.

**Recurrent Cystitis or Pyelonephritis**

Women with recurrent or persistent UTIs, especially those with diabetes, immunosuppression or urinary obstruction require antibiotic prophylaxis. Taking antibiotics every night or every other night has been found to decrease the incidence of recurrent UTI. The suppressive dose usually employed is one-quarter or one-third of that given for the management of an acute episode. Some women may relate the development of UTIs to coitus. Single postcoital doses of antibiotics, including trimethoprim, sulfamethoxazole, ciprofloxacin or other quinolones has shown to decrease the recurrence of UTIs (Table 5).

**Lower Urinary Tract Infections in Pregnancy**

When treating lower UTIs in pregnancy penicillins and cephalosporins have been shown to be safe in the first and second trimesters. As it is a folate antagonist, trimethoprim should be avoided in the first trimester, although it may be used safely in late pregnancy. Conversely nitrofurantoin and sulfonamides are safe in early pregnancy, although they should be avoided in third trimester when the former may cause a hemolytic anemia and the latter hyperbilirubinemia and kernicterus. Tetracyclines should be avoided because of their chelating action, which will lead to hypoplasia and staining of the teeth. Whilst in general erythromycin is considered safe, the estolate salt may be associated with cholestatic jaundice. Finally fluoroquinolones may affect fetal cartilage formation, and chloramphenicol may be associated with neonatal cardiovascular collapse.

Urinary Tract Infections in Women

The female genital and urinary tracts arise from the primitive urogenital sinus and develop in close proximity. Urological and vaginal symptoms due to urogenital aging often parallel each other, because they originate from a common fetal structure. Human and animal studies have identified estrogen receptors in the tissues of the vagina, urethra, bladder and pelvic floor. Estrogen deficiency, particularly when prolonged is associated with a wide range of urogenital complaints including frequency, nocturia, incontinence, UTIs and the "urge syndrome". These may coexist with vaginal symptoms of dryness, itching, burning and dyspareunia. Iosif and Bekassy20 studied 2,200 women aged 61 years and found that the incidence of lower genital tract disorders was high with 49% of women having some symptoms. UTIs are also very common in older women, leading to substantial morbidity.

### Effect of Aging on the Urinary Tract

In women, older age (and presumably concomitant lower estrogen concentrations) is associated with several genitourinary changes, such as atrophy of the bladder trigone, diminished sensitivity of the α-adrenergic receptors of the bladder neck and urethral sphincter and thinning of the urethral mucosa. Urodynamic studies have shown that the urethra and bladder become less efficient with age. Elderly women have a reduced urine flow rate and increased residual urine volume. In addition, detrusor pressures at urethral opening and closure during voiding fall. With a decline in blood flow due to estrogen deficiency, important immune system functions may also be affected, facilitating in combination with the wide urethra, microbial migration into the urinary bladder. This together with the vaginal reservoir of urinary pathogenic microorganisms makes it understandable that there is a high frequency of symptomatic and ASB as well as recurrent cystitis.21

### Estrogens and Recurrent Urinary Tract Infections

Alternations in the vaginal flora following menopause, place women at an increased risk of UTIs, particularly if they are sexually active. There is a rise in vaginal pH and a fall in the number of lactobacilli, allowing colonization of Gram-negative bacteria which act as uropathogens. Many studies have shown that estrogen reverses these changes, an effect which enables it to be used for either treatment or prophylaxis of recurrent UTI.

### Management

The first step is a careful consideration of the history and analyzing symptomatology. A careful gynecological examination will assess the degree of atrophy and the presence of infection. A wet vaginal smear, Pap smear and an analysis of midstream urine sample are performed if indicated. Local estrogen therapy is suitable for urogenital atrophy and the symptoms caused by it. Estrogen preparation in the form of vaginal cream, pellets or rings can be prescribed. If the patient is satisfied with the relief it provides, maintenance dosage can be given for a more prolonged period. Micronized estriol cream 0.5 mg/day has a specific action on vaginal and lower urinary tract epithelium. It does not cause endometrial proliferation and hence there is no withdrawal bleeding and no supplementary progesterone is required.

If the symptoms are not relieved after 4 weeks of topical estrogens the patient needs further evaluation. Estrogen therapy may be stepped up. In addition to local estrogen, systemic therapy may also be started if there are no contraindications.

### Conclusion

Urinary tract infections are very common in women. These infections must be identified, treated and sterility proven. Recurrent UTIs should be treated rigorously and may be

able to be prevented. Estrogens may be effective when used for prophylaxis against recurrent UTIs in postmenopausal women.

REFERENCES

INTRODUCTION
In clinical practice, the gynecologist is presented with a variety of urinary disturbances related to the bladder and the urethra. In order to understand these, it is essential to understand the physiology of micturition and its control. In this chapter, we will first deal with the micturition physiology followed by problems of urinary incontinence and their management in detail.

MICTURITION
Micturition is defined as the process by which the urinary bladder empties itself when it becomes filled. The main actions involved in micturition are:

- Progressive filling up of the urinary bladder till the tension in the wall crosses a threshold value.
- This is followed by a nervous reflex known as micturition reflex (Fig. 1) (Flow charts 1A and B) which causes micturition or at least a conscious desire to urinate.

Once the micturition reflex becomes powerful enough it causes another reflex through the pudendal nerves to the external urinary sphincter to inhibit it. If this inhibition is more powerful than the voluntary constriction signals to the external sphincter from the brain, urination will occur.

Approximate normal cystometric values in women (Fig. 1):

**Point 1**: Residual urine—Less than 50 mL
**Point 2**: First desire to void—150–250 mL
**Point 3**: Cystometric capacity—400–600 mL
**Point 4**: Maximum detrusor pressure during filling—Less than 15 cm of H$_2$O
**Point 5**: Bladder compliance index—20–100 mL/cm of water measured 60 seconds after reaching cystometric capacity

**Point 6**: Maximum detrusor pressure during voiding—Less than 70 cm of H$_2$O
**Point 7**: Peak urinary flow rate—More than 15 mL/sec
**Point 8**: Absence of systolic detrusor contractions during bladder filling.

Bladder Muscles
The bladder consists of a smooth muscle chamber made up of two parts, viz.

1. The body, which is the main portion of the bladder in which the urine collects.
2. The neck, a funnel shaped extension passing anteriorly and inferiorly into the urogenital triangle and connects to the urethra.
The smooth muscle of the bladder is made up of muscle fibers extending in all directions with cells fusing with each other such that an action potential can spread throughout the detrusor muscle leading to contraction of the entire bladder muscle at once.

**Bladder Sphincters**

- Internal sphincter is 2–3 cm long and is composed of detrusor muscle interlaced with large amount of elastic tissue. It keeps the bladder neck and posterior urethra empty thus preventing bladder emptying till the bladder pressure goes above a critical threshold.

- External sphincter is made up of voluntary skeletal muscle and is under voluntary control of the nervous system thus preventing urination even against the involuntary controls.

**Bladder Innervation**

This is mainly by way of pelvic nerves connecting the spinal cord through the sacral plexus mainly to segments S2 and S3. These nerves contain both sensory and motor fibers. The former are mainly responsible for detection of stretch signals especially from the posterior urethra initiating reflexes causing bladder emptying. The motor fibers consists mainly of parasympathetic fibers innervating the detrusor muscle. The skeletal motor fibers of the external sphincter are supplied by body somatic nerves fibers via pudendal nerves (Fig. 1).
Tone of the Bladder and the Cystometrogram

Cystometrogram is the solid curve which shows the approximate changes in the intravesical pressure as the bladder fills up with urine. Cystometry is the technique which studies the pressure-volume relation of the bladder and is used to assess bladder sensation, bladder compliance and detrusor activity.

THEORIES OF FEMALE CONTINENCE

Pressure Transmission Hypothesis
- Female urethra—intra-abdominal portion and extra-abdominal portion
- Increase in intra-abdominal pressure
- It is transmitted simultaneously to the bladder and the proximal urethra to prevent leakage of urine.

Hammock Hypothesis

This hypothesis emphasizes anatomical principles of female continence. According to this hypothesis, continence is maintained by compression of urethrovesical junction against the hammock of the anterior vaginal wall and the pubocervical fascia during an increase in the intra-abdominal pressure.

URINARY INCONTINENCE

Urinary incontinence is defined as the involuntary loss of urine posing a social or hygienic problem and which is objectively demonstrable.
- Stress urinary incontinence (SUI) is defined as urinary loss which occurs with sudden elevations of the intra-abdominal pressure without detrusor contractions.
- Genuine stress incontinence is defined as involuntary loss of urine when the intravesical pressure exceeds the intraurethral pressure in the absence of detrusor activity. This term is used only for a patient who has undergone urodynamic testing. The new term recommended by the international continence society is urodynamic stress incontinence.

Incidence

Stress urinary incontinence can affect women of all ages but has a prevalence of 10–30% in women between the ages of 15 years and 64 years.

Factors Contributing to Stress Incontinence

Basically SUI is determined by an interaction of three determinants:
1. The biologic strength of the sphincteric mechanism
2. The level of physical stress placed on the continence mechanism
3. The woman’s personal and cultural expectations about urinary incontinence.

Factors Contributing to Urethral Integrity

Extrinsic Factors
- Endopelvic fascia and integrity of its lateral attachments
- Levator ani muscles and their strength
- Connections of levator muscle complex with the endopelvic fascia
- Coordination of levator muscle contraction with factors which increase the intra-abdominal pressure.

Intrinsic Factors
- Sympathetic innervation and tone (α-adrenergic)
- Striated urethral muscle
- Mucosal coaptation of the urothelium
- Vascular congestion of submucous venous plexus
- Smooth muscle of urethral wall and blood vessels
- Elasticity of urethral wall.

Evaluation of Stress Urinary Incontinence

- Stress urinary incontinence may be mild requiring an increase in pressure by 70–80 cm of water for it to occur or may be very severe requiring only 20–30 cm of water rise in the pressure.
- The amount of urine lost at a given time is only a few drops which is a very important feature of the diagnosis.
- Soreness and excoriation of the vulva due to frequent repeated leaking of urine.
- Patient feels a social outcast and avoids leaving the house.
- Frequent attempts at emptying the bladder to keep herself dry
- Incontinence occurs irrespective of the degree of fullness of the bladder although very high pressure may be required to cause urinary leakage when the volume in the bladder is low.

Demonstration of Stress Urinary Incontinence Clinically

As the factors contributing to SUI become more and more clearly understood, SUI can be separated into three broad types:
1. SUI due to anatomic hypermobility of urethra
2. SUI occurring due to intrinsic sphincteric deficiency or weakness
3. Fixed urethra with failure of the intrinsic sphincter.
   The former is more prevalent and occurs due to faulty urethral closure under situation of stress. It accounts for 80–90% of all cases of SUI. The latter although less common, is more difficult and challenging as far as treatment is concerned. Thus, while demonstrating SUI, the main factor
METHODS OF EVALUATION OF URETHRAL SUPPORT

Clinical Examination

This is the quickest and simplest way of evaluation of urethral support. It involves inspection of the urethra and bladder neck while the patient is at rest and then during maximum straining.

Rotational descent of the bladder neck can be easily demonstrated. Leakage of urine with increase in the intra-abdominal pressure can also be demonstrated provided the patient has not emptied the bladder immediately before examination.

It is important to note that urinary leakage in some patients can be demonstrated only when the patient is standing and this makes it necessary to examine the patient in standing position as well. The character and timing of urethral leakage should also be noted.

Q Tip Test

It is a simple test to evaluate urethral axial mobility. A sterile lubricated cotton tipped swab is placed in the urethra up to the bladder neck. The resting angle of the urethral axis is first measured using a goniometer. The patient is then asked to strain maximally and the angle of excursion of the swab is measured. If the maximum straining angle is more than 30°C, it provides significant evidence of urethral hypermobility. However, it is to be kept in mind that this test is indicative of urethral hypermobility and not diagnostic of SUI.

Bonney’s Test

This test, discussed by the late Victor Bonney, aims at seeing whether an uplift of the urethrovaginal stem will stop the incontinence during times of raised intra-abdominal pressure, thus giving a guidance to the type of surgery required. With the patient in dorsal position, light pressure is applied at the sides of the upper urethra without causing an uplift. A positive test is indicated by control of urinary leakage from the vagina with closure of the internal sphincter by pressure. The main usefulness of this test is not to demonstrate patient remaining dry but to find patient who continue to leak in spite of correction of normal anatomic support, thus suspicious of having a significant element of intrinsic urethral sphincter weakness or deficiency.

Investigations

- **Fluoroscopy** of the bladder for identification of patients in whom the bladder neck is gaping open at rest, in standing position. These patients are at high-risk of failure to improve from standard supportive bladder neck suspension procedures.
- **Lateral urethrocytography** (Micturating cystourethrogram or micturating cystogram) involves filling of the bladder with a radiopaque contrast medium through a urethral catheter and then taking lateral radiographs, at rest, while straining and during micturition. In a normal person, the posterior urethrovaginal angle is lost during voiding such that the urethra and the trigone come into line opening up the bladder neck. In patients with incontinence, the posterior urethrovaginal angle is also lost. This may be apparent when the woman is standing or sitting quietly in severe cases; in mild to moderate case it is apparent only with straining.
- **Cystourethroscopy** can be used in identification of poorly functioning urethras, e.g. scarred urethras in which the urethral lumen remains open throughout the examination making visualization of the bladder interior possible from the distal urethra.
- **Urethral pressure profile** involves measurement of the pressure along the entire urethral length using a special catheter with 3 microtop pressure transducers placed 6 cm apart pulling it out from the bladder to the outside through the urethra at a fixed rate. All along the transducer keeps measuring the intravesical pressure till it enters the urethra when the pressure rises and peaks at the point of maximum urethral pressure. The difference between the maximum urethral pressure and the intravesical pressure gives the maximum urethral closure pressure, i.e.

  $$ \text{Maximum urethral closure pressure} = \text{Maximum urethral pressure} - \text{Intravesical pressure} $$

However, urethral pressure profile determination test is not very sensitive as the pressure readings can vary depending on the orientation of the transducer, the rate of withdrawal of the catheter, the bladder volume, the patient’s position, etc. Also there exists an overlapping of the pressure values between normal patients and those with SUI. Hence, this test could not stand the test of time and search for more sensitive tests continued.

- **Leak point pressure determination** is the total intravesical pressure required to produce SUI in a patient. According to McGuire, patients with leak point pressures of less than 60 cm of water have severe incontinence due to intrinsic sphincteric deficiency.

Other Varieties of Incontinence

- **Ure incontinence**: It refers to urine loss which is accompanied by a strong desire to urinate (urgency)
- **Reflex incontinence**: Abnormal spinal cord reflex activity in the absence of a normal desire to micturite
- **Overflow incontinence**: Passive elevation of the bladder pressure above maximum urethral pressure due to vesical distension
- **Detrusor instability**.
Stress Urinary Incontinence

MANAGEMENT

• Careful history and examination (as already described) including:
  - Chief complaints
  - Duration
  - Any special circumstances or precipitating events leading to SUI
  - Progression.
• History of previous attempts at treatment and some idea of severity
• Frequency volume bladder chart or maintenance of a urinary diary, this should include:
  - Volume of each void
  - Time at which voiding occurred
  - Time and amount of fluid intake
  - Any episodes of incontinence and any special events leading to them to be noticed
  - Episodes of frequency (more than 7 voids/day), nocturia (awakening from sleep with the need to urinate), etc.
• Treatment history
  - Medical
  - Surgical
• Complete examination
  - General
  - Neurologic screening tests especially lower limbs and perineum
  - Urogynecologic examination
  - Investigation
  Management of SUI is almost always considered to be surgical although this is not always required or true. Surgery should be advised and undertaken only when the problem is severe enough warranting correction and when the patient is fit for the same.
  Although the complete interaction between the urethral tone, bladder neck and urethral mobility and the state of pelvic innervation remains incompletely understood, recent understanding of pelvic anatomy suggest that the main support of this region comes from the pelvic musculature especially the levator ani complex. The periurethral fibers of these muscles maintain tone over a long period of time and increase the tone suddenly to compensate for any increase in the intra-abdominal pressure. Thus, improvement in the strength of these muscles by rehabilitation through physiotherapy and exercise can increase its ability to cause effective urethral closure and maintain continence.

Kegel’s Exercises

Aim

• To strengthen the striated urogenital sphincter
• Improve the support of the proximal urethra.

Principles

• It must be supervised, done regularly and aided by some form of feedback to provide judgement of progress, e.g. pneumatic biofeedback perineometer.
• It requires an intensive program for 3 months with pre- and post-treatment urodynamic evaluations.
• It involves tensing the musculature for 5 seconds each 15–20 times per session and three such sessions per day.
• Gardener and Fonda have stated that urinary incontinence in older age can be cured or significantly improved in 60% of cases with conservative management.
• Dougherty et al. showed that 16 weeks of pelvic floor exercises produces significant improvement in urinary incontinence.

Pharmacological Treatment

• As the adrenergic activity from the sympathetic nervous system is the main element maintaining the tone of urethra and bladder neck, an adrenergic agonist can be used to treat SUI.
  The agents tried till date are:
  - Ephedrine 25–50 mg QDS
  - Pseudoephedrine HCl 30–60 mg QDS
  - Phenylpropanolamine HCl 50–75 mg BD
  - Imipramine 10–25 mg TDS
  - Main side-effect: Hypertension due to increase in vascular tone by these agents.
• Anticholinergic agents:
  - Propantheline bromide 15–30 mg QDS
  - Methantheline bromide 50 mg QDS
  - Hyoscine sulfate 0.37–0.75 mg BD/tabs
• Calcium-channel blockers: Anticholinergic action (e.g. Terodiline HCl 12.5–25.0 mg BD).

Estrogen Replacement Therapy

This therapy can be adopted in case of postmenopausal women with urogenital atrophy due to estrogen depletion.

Electrical Nerve Muscle Stimulation Therapy

This involves the passage of an electric current either transvaginally or transrectally in a continuous or intermittent manner to the muscles of pelvic floor causing their contraction and reflex inhibition of detrusor activity.

In Case of Associated Detrusor Instability

• Bladder retraining/bladder drill regime
• Drug therapy like antispasmodic agent, e.g. oxybutinin chloride 5–10 mg TDS/QDS, flavoxate HCl 200 mg QDS.
• Prostaglandin synthetase inhibitor, e.g. mefenamic acid.
**Treatment of any Associated UTI**

Surgical treatment of SUI: More than 200 different surgeries have been described so far for the treatment of SUI and this itself suggests that an ideal surgery applicable to all patients has not been devised yet.

**CLASSIFICATION OF OPERATIONS FOR STRESS URINARY INCONTINENCE**

- Anterior colporrhaphy with Kelly’s plication of paravesical tissue at the bladder neck
- Abdominal bladder neck suspension procedures designed to correct urethral hypermobility
  - Retropubic bladder neck suspension
    - Marshall Marchetti Krantz surgery
    - Burch colposuspension
  - Paravaginal bladder neck suspension
    - Paravaginal defect repair
    - Vaginal obturator shelf-procedure
  - Needle suspension procedures
    - Pereyra procedure
    - Modification of Pereyra procedures—Raz, Stamey, etc.
- Operations to correct intrinsic sphincteric deficiency:
  - Sling operations
    - Organic materials: Autologous—rectus fascia and lata, etc. Heterologous—procrine dermis, ox dura, etc. Synthetic—polypropylene
    - Tension free vaginal tape
  - Artificial urinary sphincter
  - Mechanical devices.

**Anterior Colporrhaphy**

First described by Howard Kelly in 1914.

- It is an attempt to cure SUI by stabilizing the suburethral fascia thus preventing urethral hypermobility.
- It probably works by supporting the urethra and the bladder neck elevation of the bladder neck, preferably above the lowest bladder level or by supporting the bladder neck and kinking the urethra.
- The main indication is in frail elderly women with prolapse and mild genuine SUI.

**Advantages**

- Low morbidity
- Less postoperative pain
- Early mobility.

If genuine SUI is more marked, it can be combined with Stameys repair or periurethral injections with very little increase in morbidity.

This surgery has led to dissatisfaction as far as the results are concerned due to higher recurrence rate and potential narrowing and scarring of vagina postoperatively.

**Abdominal Bladder Neck Suspension Procedures Designed to Correct Urethral Hypermobility**

**Techniques for Retropubic Bladder Neck Suspension**

First described by Dr Marshall, Marchetti and Krantz (MMK) of Cornell University Medical Centre in 1949. These operations correct bladder neck displacement and urethral hypermobility by surgical suspension of these structures using an operation performed in the space of Retzius which is a potential space outside the peritoneal cavity within the bony anterior pelvis and is full of loose areolar connective tissue with varying amount of fat. The main underlying principle is stabilization of the endopelvic fascia to various fixed points in the retropubic space.

- The MMK procedure consists of taking a series of sutures in the endopelvic fascia along the urethra up to the level of bladder neck and fixing it into the periosteum of symphysis pubis.
- The Burch procedure includes fixation of the endopelvic fascia to the ilipectineal ligament of Cooper.
- The paravaginal repair involves reattaching the endopelvic fascia to the arcus tendinous.
- The vaginal obturator shelf procedure described by Turner Warwick consists of suturing the endopelvic fascia to the fascia covering the obturator internus muscle.

**Mechanism of continence with bladder neck suspension procedures:**

- The MMK procedure works by elevation of the bladder neck along with restoration of the urethrovescical anatomy leading to a valvular effect due to movement of the bladder neck and trigone behind the symphysis.
- Burch’s colposuspension works by an increase in the outflow resistance.

**Complications of retropubic bladder neck suspensions:**

- Kinking of urethra in unnatural position
- Postoperative voiding difficulty
- Osteitis pubis (in case of MMK operation)
- Chronic irritative voiding symptoms
- Uncorrected cystocele
- Predisposition to enterocoele
- Increased residual volumes and reduced flow rates
- De novo detrusor instability.

**Results of colposuspension (from different authors):** The continence rate following colposuspension reported by various authors ranges from 73% to as high as 90.3%.

**Results of colposuspension as secondary procedure:** When performed as a secondary procedure, the continence rate was between 63% and 82.5%.
Randomized study of Burch versus abdominal paravaginal defect repair showed a 100% versus 72% success rate.

**Needle Suspension Procedures**

- First described by Armand Pereyra in 1959.
- It consists of urethral suspension by a combined abdomino-vaginal approach in which a special long needle is used to carry the suture through the space of Retzius and this suture is fixed at two points viz. the perivesical fascia and the abdominal fascia. The bladder neck is thus suspended between the two sets of sutures.

  **Stamey’s modifications:**
  1. Use of intraoperative cystourethroscopy to avoid trauma to the bladder and to ensure that the suspensory suture is not passing through the bladder. Also may help in determining the tightness of the sutures.
  2. Use of small (1 cm) Dacron bolster threaded over the suspensory sutures to act as a buttress or a stopper avoiding pulling out of the suture. Closure of the vaginal incision should be done with absorbable material before the suspension sutures are lifted up and tied over the abdomen as the vaginal incision becomes inaccessible and recedes behind after the suspensory sutures have been tied off.

**Complications**

- Voiding difficulty postoperatively due to pulling of the sutures very high or tying them very tightly
- No definite endpoint of sutures elevation, thus it may remain too loose or too tight
- Pull through of the sutures in patients with poor peri-urethral and perivesical tissue
- Chronic pain due to twisting or pulling of the sutures
- Infection, erosion or granulation formation if dacron bolsters are used
- Hemorrhage from the veins in the space of Retzius
- Damage to bladder or urethra.

**Advantages**

- Quick procedure
- Technically easy
- Can be easily combined with other surgeries like vaginal hysterectomy
- Useful in morbidly obese patients where other procedures may be technically difficult.

**Long-term Results**

- Kevelighan et al.—subjective cure rates of 45% at 2 years, 18% at 4 years and only 6% at 10 years.
- Kohli N et al.—comparison of anterior repair versus transvaginal needle suspension showed a recurrence rate of 7% in the former against 33% in combined procedures.

**Bone Anchors and Needle Suspension Techniques**

Nowadays, commercially available kits have been introduced for performing bone anchored suspension procedures, e.g. vesica technique—device used to anchor the abdominal end of the sutures to the pubic bone.

**Advantages**

- Easy to perform
- Fast procedure
- Avoids the potential weakness at the rectus fascia by using bone as the anchoring point
- Low surgical morbidity and fast recovery
- Very good short-term results.

**Disadvantages**

- Costlier procedure
- Risk of osteomyelitis
- Long-term success results are still awaited.

**OPERATIONS TO CORRECT INTRINSIC SPHINCTERIC DEFICIENCY**

**Sling Surgery**

These procedures are mainly designed to compensate for intrinsic sphincter weakness or deficiency although it prevents abnormal urethral descent to some extent.

**Indications**

- Complicated SUI cases
- Previously failed surgery for SUI
- SUI following pelvic fracture
- SUI with chronic obstructive pulmonary disease (COPD)
- Massive genital prolapse with associated SUI
- Congenital urethral abnormalities.

**Principle**

Supporting the urethral bladder neck in a hammock providing both elevation and partial compression of the urethra.

**Procedure**

Insertion of a sling using a combined vaginal and abdominal procedure, a vaginal approach alone or a supra-pubic technique alone with blind dissection beneath the urethra and bladder base have been described. The common feature of sling surgery is to pass a strip of material beneath the urethra or the bladder neck.

- **Goebel Stock Frangenheim operation:** It involves the placement of a fascia lata sling under the bladder neck
and anchoring its two ends to the rectus fascia through the space of Retzius on either side.

- **Adridge procedure**: It involves fixation of strips of rectus fascia to the endopelvic fascia through the space of Retzius using small permanent sutures.
- **McGuire’s pubovaginal sling**: Uses a small piece of rectus fascia as the hammock in which the urethra rests.

### Tension Free Vaginal Tape

Tension free vaginal tape (TVT) is a new sling procedure which is minimally invasive and involves passage of polypropylene tape around the mid-urethra through a vaginal incision providing a resilient platform under the mid-urethra to maintain continence against an increased abdominal pressure.

#### Indications for Tension Free Vaginal Tape

- Intrinsic sphincteric efficiency
- Previous failed anti-incontinence surgery
- Co-existent morbidities viz. COPD, obesity, etc.

#### Procedure

- Done under sedation or GA or spinal anesthesia or ethylene dibromide
- Bladder drained by 18 F catheter which is left in situ for the initial part of the procedure
- 0.5 cm incisions made at the superior margin of the pubic bone, 2.5 cm from the midline on either side
- 1 cm midline incision in the vaginal mucosa under the mid-urethra
- 1 cm tunnel created between vaginal mucosa and pubocervical fascia lateral to the mid-urethra on both sides
- First needle with tape attached is passed through the suburethral incision into the left tunnel and then going upward through retropubic space in close contact with posterior surface of pubic bone till it penetrates the suprapubic incision on left side
- Foleys removed, bladder filled with saline and cystoscopy performed for evidence of needle perforation
- Foleys reinterted and procedure repeated on opposite side after ensuring that the tape is placed flat under the mid-urethra without any twist
- Both ends of the tape are cut from their needles and grasped with clamps
- 0.5 cm gap created between the mid-urethra and the tape using a clamp to ensure tension free placement
- Plastic sheath over the tape removed
- Each end of the tape is cut just below skin level
- Skin closed with 4-0 suture
- Vaginal mucosa closed with 3-0 suture
- Postoperative trial of voiding and measurement of residual volume (aim at residual of less than 100 ml.).

### Complications and Risks

- Postoperative voiding difficulty
- Bladder perforation, bowel injury, urethral injury
- Urethrovaginal fistula
- Bladder erosion unrecognized at the time of surgery
- Vascular injury and hemorrhage
- Rarely ilioinguinal nerve entrapment, urethral erosion, vaginal erosion, necrotizing fasciitis, delayed bowel erosion.

### Outcome

- Similar objective cure rates on comparison with Burch colposuspension at 2 years postoperatively (81% for TVT, 80% for Burch).
- Women with recurrent SUI after failure of previous surgery can benefit from TVT. Cure rates of 81–85% reported.
- Effective for intrinsic sphincteric deficiency: Up to 74% cure rates and 12% significant improvement reported.

#### Transobturator Tape Sling

- Placement of a polypropylene sling under the mid-urethra using a curved needle inserting the tape around the ischiopubic ramus in horizontal plane through obturator foramina.
- Cure rates similar to TVT with lesser incidence of bladder injury.

#### Suprapubic Arc Sling

- Involves placement of a polypropylene mesh under the mid-urethra.
- The technique involved is different from a TVT in that it employs passage of a needle above the pubic bone down through a suburethral vaginal incision. The tape is then attached to the needle and pulled up above the pubic bone.

### Complications

- Retropubic bleeding and hematoma formation occasionally requiring drainage and/or transfusion
- Small bowel injury
- Bladder injury
- Postoperative voiding difficulty.

#### Periurethral Injections (Bulking Agents)

Periurethral injections was first described by Murless using phenol in 1938.

**Mechanism of action**: Bulking up the bladder neck tissues causing the urethral mucosa to coapt in situations of raised intra-abdominal pressure and increases urethral closure pressure.
Stress Urinary Incontinence

**Procedure**
- Outpatient procedure
- Done usually under local anesthesia
- Transurethral or periurethral injection under cystoscopic guidance with a 22 gauge spinal needle with bevel facing medially and angled toward the bladder neck
- Usually 20 mL of material is required
- Similar procedure repeated on the opposite side.

**Materials Used**
- Teflon
- Autologous fat
- Contigen—Glutaraldehyde cross linked with bovine collagen
- Urethrin—Polytetrafluoroethylene micropolymer particles
- Micronized silicone rubber particles.

**Complications**
- Urinary infection
- De novo detrusor instability—rare
- Hypersensitivity especially to bovine collagen
- Expensive
- Long-term effects are difficult to assess.

Berman CJ et al. showed a 26.7% rate with collagen injection versus 71.4% success rate with fascia lata sling surgery.

**POSTOPERATIVE MANAGEMENT**
- Adequate bladder drainage without overdistension of a traumatized bladder which may lead to long-term voiding dysfunction and affect the success of the surgery. The catheter is left undisturbed for at least 24 hours before any attempts at voiding. The purpose is to provide regular and complete voiding without overdistension at any point.
- Adequate nursing care.
- All patients should be taught clear intermittent self-catheterization which can be done after each void to judge the progress of voiding allowing modification of the voiding schedule.
- Placement of a suprapubic catheter or silicone Foley catheter through a bladder incision. When voiding trials are begun, the patient is asked to record the volume of urine voided while the suprapubic has been kept closed. Thereafter the suprapubic is opened up for about 20 minutes to see the post void residual volume. When the voided volumes are large and the post void residual volume is low, the suprapubic can be removed.
- Adequate antibiotic cover.
- Pharmacological measures to treat urgency, frequency and urge incontinence which may occur in the first few weeks.

**FAILURES OF SURGERY**

**Causes**
- Episodic incontinence
  - Stress incontinence
  - Recurrence of SUI
  - Detrusor instability
- Urge incontinence
  - Prior to surgery
  - Detrusor instability
  - Wet without warning
  - Detrusor instability
  - Defective voluntary control
- Continuous incontinence
  - Retention with overflow
  - Fistula (urethral, vesical, ureteric)

**CAUSES OF RECURRENT STRESS URINARY INCONTINENCE**
- Failure to elevate bladder neck
- Failure of alignment of the urethra to posterior aspect of the pubic symphysis
- Lack of support to the proximal urethra and bladder
- Postoperative surgical fibrosis
- Properly elevated bladder neck—sling procedure
- Functionless rigid urethra—artificial urinary sphincter
- Detrusor instability—antispasmodic therapy, e.g. Oxybutynin, flavoxate, etc. bladder ret raining regimes.

**BIBLIOGRAPHY**

Genital Fistula

**CHAPTER 71**

Vinita Das, Anjoo Agarwal
*(Chapter updated by Urvashi Verma)*

**INTRODUCTION**

Genital fistula is one of the most tragic occurrences of a woman’s life making her a social outcast. It is basically an abnormal communication between urinary or gastrointestinal and genital tract, either acquired or congenital with involuntary escape of urine or feces into the vagina. The incidence of genital fistulae varies from region to region as do the causative factors.

Genital fistulae may be divided into two broad categories:

1. Urinary fistulae
2. Fecal fistulae

Uterocutaneous fistulae is a rare entity. Most fistulae result either from obstetric trauma or during gynecological surgery.

**URINARY FISTULAE**

Depending on the anatomical site they may be divided into the following:

- **Ureters:**
  - Ureterovaginal
  - Ureterocervical
  - Ureterouterine
- **Bladder:**
  - Vesicovaginal fistula (VVF)—High, mid, low, massive
  - Vesicocervical
  - Vesicouterine (Fig. 1)
- **Urethra:**
  - Urethrovaginal.

**INCIDENCE**

Incidence of genitourinary fistula is 0.5–3% among gynecological admissions in referral hospitals of the developing countries although accurate figures are difficult to obtain.

Five hundred new cases a year are currently being treated at the Addis Ababa Fistula Hospital (J Hamlen 1982, personal communication).^3^ Newcastle survey of 1969–1970 (Lawson 1977, personal communication) shows that 350 vesicovaginal fistulae are treated each year in England and Wales.^3^ In the developing countries fistulae are most common due to obstetric causes while in developed countries it is injury at gynecological surgery which is the main contender. Obstetric fistulae due to obstructed labor were seen in 0.3–3.7% of admission to gynecological wards in India and Nepal (Shah 1989).^4^ Prema Naidu from Hyderabad (India) reported that out of 208 fistulae examined by her in 1962, obstetric causes accounted for 201 cases.^5^ Rao (1972),^6^ Abbo and Mukhtar (1975)^7^ Gunarathe and Mati (1982),^8^ Taheib (1983)^9^ also reported an 85% incidence of obstetrics fistulae from Asia and Africa.

In contrast, in Moir’s series of 350 vesicovaginal fistulae in the UK, 268 were due to gynecological causes and only...
82 were a result of obstetric trauma. Similarly in the United States, 82% of VVF are small fistulae in vaginal vault that appear after total abdominal and vaginal hysterectomy for benign disease.

### ETIOPATHOGENESIS

#### Obstetrical Factors

Vesicovaginal fistula (Fig. 2) is the most common type of fistula. In developing countries most common cause is obstetrical trauma, although various etiopathological factors are as follows.

**Obstructed Labor**

In obstructed labor it results from prolonged compression effect on the bladder base between the presenting part and the symphysis pubis followed by ischemic necrosis of the tissues, which slough off leading to fistulous communication. Such fistulae present within a week of delivery.

**Traumatic**

- Injury to the bladder may occur in destructive procedures such as craniotomy, decapitation, evisceration either by instrument itself or by bony spicules of the fetal skull
- Difficult forcep delivery may result in trauma to the soft tissues
- Symphysiotomy
  
  Such type of fistulae present within 24 hours of delivery.

**Rupture Uterus**

Distal extension of the rupture itself may involve the bladder and cause fistulae formation.

- Besides fistula formation between bladder and genital tract, fistula can also occur between ureter or urethra and genital tract
- Urethral sloughing can occur in prolonged second stage of labor, especially in obstructed labor. Injury to urethra can occur even during urethral coitus or illegal abortion. Urethra can avulse also during vaginal delivery
- Injury to ureter can also occur while applying forceps before full dilatation of cervix or during cesarean section or cesarean hysterectomy

*Postpartum use of intravaginal caustic agents may also cause erosion of vagina leading to VVF.*

#### Obstetrical Abdominal Operations

- Cesarean section especially repeat cesarean section can result into fistula formation because of presence of adhesions.
- Cesarean hysterectomy done for rupture uterus can also cause fistula formation when bladder is edematous and high up. Injury may be direct or ischemic following a part of bladder wall being caught in the suture or due to inadequate mobilization of the bladder.
- Retrovesical hematomas may also result into fistula formation. Such fistulae present from 7 days up to 3 months.

#### Gynecological Surgical Injuries

**Abdominal Hysterectomy**

Vesicovaginal fistula develops in 0.5–1% of patients undergoing an abdominal hysterectomy. The chances of development of VVF are more in total abdominal hysterectomy because of close proximity of cervix with bladder. Injury to bladder base is more common due to the following points (Fig. 3):

- Inadequate mobilization of bladder inferiorly and laterally
- Vigorous and blunt dissection in an improper plane between the base of bladder and pubovesicocervical fascia covering the cervix
- At the time of vault closure suture may take a bite through the bladder base leading to gradual necrosis of bladder wall and formation of VVF, which manifests after first week of surgery
- Use of prolonged or deep diathermy for hemostasis at bladder base may also lead to fistula formation
- Abdominal hysterectomy done in previously irradiated tissues or previous cesarean section, or in women with pelvic inflammatory disease, diabetes mellitus, concurrent infection, vasculopathy or tobacco abuse are more at risk.
Genital Fistula

and sloughing of neoplastic tissue in vesicovaginal septum leading to fistula formation. Radiotherapy, even as a latent effect in 1–2 years time causes end arteritis obliterans leading to ischemic necrosis and sloughing. These fistulae are usually located at the bladder neck and upper urethra. Malaplication of brachytherapy implants may also lead to fistula formation.

Infections

Chronic granulomatous lesion may lead to fistulae formation.

Vaginal Tuberculosis

Formation of granulomas and scarring may lead to weakening of wall and formation of VVF.

Lymphogranuloma Venereum

*Lymphogranuloma venereum* causes vesicopustular eruptions leading to ulceration and fibrosis involving bladder wall and formation of urethrovaginal fistula (UVF).

Actinomycoses

A gram-positive anerobic slowly progressive bacterial infection, which causes violation of normal tissue plane creating draining sinuses which may reopen to form a fistula.

Others

Endometriosis: Congenital

*Symptoms and diagnosis:* The typical history of a fistula due to pressure necrosis is that of a prolonged labor (often unattended) resulting in a stillbirth with incontinence of urine and in some cases also feces a few days later.

Following direct injury during surgery, incontinence usually appears immediately after the delivery or surgery. In postradiation cases, fistula may form many years later.

With a small fistula the urinary leakage is slight and sometimes depending on the position of the patient the woman may be able to void urine in good quantities.

With larger fistulae the woman suffers from a true incontinence of urine, i.e. continuous dribbling of urine.

Most fistulae are painless but fistulae resulting from irradiation can cause severe pain which may be aggravated by movement.

Bladder injury must be suspected in postoperative patients with abdominal pain, distension, paralytic ileus, hematuria or severe bladder irritability.

Continuous trickle of urine down the vagina produces vaginitis and vulvitis with attendant soreness. Incrustation of phosphates may form in the vagina, and in long-standing cases there may be extensive excoriation of vulva, groin and thighs.
On examination, care must be taken to distinguish between the true incontinence of a fistula and overflow or stress incontinence. Most fistulae can be easily visualized on a per speculum examination. Filling the bladder with a dilute solution of methylene blue may help in visualizing small fistulae.

Moir’s three tampon test is useful in differentiating between a ureterovaginal and a VVF and in identifying the level of a VVF. In this test, three cotton tampons are placed in the vagina in tandem. Methylene blue is instilled in the bladder. The patient walks about for 10–15 minutes, and the tampons are removed and examined. If the lowest tampon is wet and stained blue, the patient may be presumed to have transurethral urinary incontinence and no fistula. If the upper tampon is wet and blue, a VVF is indicated. If the upper tampon is wet but not blue, a ureterovaginal fistula is the likely diagnosis.

Cystoscopy is useful in identifying the level of a fistula and its relation to ureteric orifices but it is difficult in large fistulae as the bladder cannot be distended adequately. In these cases the air method of Kelly and the carbon dioxide technique of Robertson are useful modifications. At times more than one VVF may be present. If the single fistula is identified it cannot be assumed that it is the only one present.

Excretory urography is useful in delineating the exact site and number of fistulae. Sonography has recently been shown to be complementary to above investigations in evaluation of patients with obstetric fistulae. Various genital abnormalities not revealed by intravenous urography were detected by sonography. These included cervical injuries and VVF showing ‘flat tire’ sign and hourglass deformities.

A urinalysis and urine culture must be done to identify the presence of a concomitant infection. In case of a small fistula sample may be collected by a midstream clear catch method or by catheterization to avoid continuous dribbling, urine may be collected on a sterile speculum and sent for analysis.

When injury is suspected at the time of surgery then intravenous indigo carmine must be injected to check the integrity of the urinary tract.

**URETEROVAGINAL FISTULA**

Close anatomical association between ureter and genital organs may lead to ureteric injury during gynecological surgery.

*Incidence: 0.5–1% of all pelvic operations.*

- At or below the pelvic brim
- Along the course of ureter on lateral pelvic wall above the uterosacral ligaments

- In the base of broad ligament where the ureter passes beneath the uterine vessels, about 1.5 cm lateral to cervix at the level of internal orifice
- Beyond the uterine vessels as the ureter passes in the tunnel in Mackenrodt’s ligament and turns anteriorly and medially to enter the bladder
- In the intramural portion of bladder

**Nature of Injury which can Lead to Ureterovaginal Fistula**

- Ischemia from trauma to ureteric sheath endangering its blood supply
- Ligature incorporation
- Crushing injury by clamps—necrosis
- Segmental resection either accidental or planned
- Thermal injury when diathermy or laser is used
- Injury by staplers during laparoscopic surgery

**Gynecological Operations Causing Ureterovaginal Fistula**

- *Radical hysterectomy:* Extensive surgery leading to devascularization and ischemic necrosis of the wall of terminal ureter resulting into UVF.
- *Abdominal hysterectomy:* To remove
  - A tubo-ovarian abscess
  - Extensive pelvic endometriosis
  - An intraligamentary leiomyoma
  - Ovarian remnant

**URETHROVAGINAL FISTULA**

Small isolated fistulas are caused by:

- Anterior colporrhaphy
- Urethroplasty
- Suspension or sling operations for stress incontinence
Prevention

For Obstetric Fistulae

- Community awareness for institutional deliveries can go a long way toward preventing obstetric fistulae. The fact is proven by the low incidence of such fistulae in developed countries.
- Once the patient does come late in obstructed labor such cases must be dealt by the most experienced obstetricians in the hospital to reduce the occurrence of complications.

For Gynecological Surgery

There has been a move promoting subtotal hysterectomy over total hysterectomy for benign gynecological conditions, to reduce bladder trauma. Another very important technique taught to students in gynecology is to always apply clamps as close to the uterus as possible during hysterectomy. Clamps must never be applied blindly. When bleeding occurs, proper exposure must always be obtained. Sharp dissection must be used to isolate the bladder. The performance of intrafascial hysterectomy may also help avoid bladder injury. In a series of 867 women who underwent intrafascial abdominal hysterectomy there was a bladder injury incidence of 0.4%.\(^\text{15}\)

Consequences of Genital Fistulae

Genital fistulae are a psychologically debilitating condition making the woman a social recluse, disrupting sexual relations and leading to depression and low self-esteem. Goh et al.\(^\text{16}\) concluded that all women with genital tract fistulae must be routinely subjected to psychological/psychiatric assessment and treatment.

Fecal Fistulae

Depending on the anatomical location these may be classified into:
- Enterovaginal
- Sigmoidovaginal
- Rectovaginal
- Anovaginal.

Incidence

Rao (1989) reported that 5% of urinary fistulae are associated with rectovaginal and anovaginal fistulae.\(^\text{17}\)

Etiology

Obstetric

- Third or fourth degree perineal laceration
- Prolonged labor
- Difficult forceps
- Precipitous delivery.

Surgery

- Difficult abdominal hysterectomy
- Vaginal hysterectomy
- Perineorrhaphy.

Malignancy

Cervix, vagina, rectum, uterus.

Irradiation

Inflammatory processes:
- Crohn’s disease
- Diverticulitis
- Perirectal and pelvic abscess
- Tuberculosis
- Lymphogranuloma venereum.

Others

- Vaginal trauma
- Leukemia
- Aplastic anemia
- Agranulocytosis
- Systemic lupus erythematosus
- Endometriosis.

Symptoms and Diagnosis

A small rectovaginal fistula may be entirely asymptomatic, a slight leakage of gas and seepage of feces in the vaginal discharge go unnoticed. When the fistula is a bit large there is complaint of passage of flatus per vaginum and fecal odor in vaginal discharge. Patient may complain of fecal incontinence when she has diarrhea. Larger fistulae may result in the entire contents of the bowel being evacuated through the vagina.

Rectovaginal fistulae are normally painless except those following irradiation or due to inflammatory diseases particularly Crohn’s disease.

A fistula between the ilium and vagina usually causes intense excoriation and redness of vaginal and vulvar tissues due to irritation by secretions from the small intestine.

As in urinary fistulae methylene blue is useful in delineating the fistulous tract. Barium enema, proctoscopy and barium meal are other useful investigations.

A simple test has been described for identification of small fistulae not visible on routine examination. Patient is laid in slight Trendelenburg position and a 20F urinary Foley’s catheter is placed in the anal canal with a 5 mL balloon. Air is pushed through the catheter while the water filled or soap covered vagina is observed for air bubbles.

Though comparatively less common than urinary fistulae but fecal fistulae are equally traumatic for the woman and the principles of obstetric management outlined for prevention of urinary fistulae apply in to prevention of fecal fistulae.
REFERENCES

INTRODUCTION
Genitourinary fistulas are marked by leakage of urine through the vagina and can cause great suffering and emotional distress in a woman. Occasionally, renal function can be impaired when a ureter is involved due to injury or due to inflammatory fibrosis leading to ureteric obstruction. Treatment of this morbid condition continues to evolve with medical opinion constantly debating the pros and cons of various techniques and approaches. Genitourinary fistulas can be classified into vesicovaginal, ureterovaginal, urethrovaginal and utero-vesical. In this chapter attention is directed to the diagnosis and treatment of vesicovaginal and ureterovaginal fistulas, but the basic principles remain applicable in all cases.

INCIDENCE AND ETIOLOGY
There are broadly two classes of genitourinary fistulas: (1) obstetric and (2) gynecological.

Obstetric fistulas result from prolonged obstructed labor due to cephalopelvic disproportion with resulting pressure necrosis of the anterior vaginal wall, bladder neck and proximal urethra. Obstetric fistulas occur more often in developing countries because of several factors:
- Social cultures favor early marriages—immature and relatively small pelvis bear the brunt of childbearing
- Poor nutrition resulting in stunted or distorted pelvic growth in the mother
- Lack of competent prenatal and obstetric care.

The incidence of vesicovaginal fistulas in the developing world has been estimated to be about 0.3–0.4% of all deliveries.

Genitourinary fistulas resulting from gynecological surgery are commoner in developed nations where gynecological surgery is more available. About 80% of gynecological fistulas occur after hysterectomy, especially abdominal hysterectomy. Other procedures that have been responsible for urinary fistulas are general surgical operations in the pelvis, anterior colporrhaphy or cystocele repair, anti-incontinence surgery or other urologic procedures.

Postradiation fistulas may develop several decades after completion of radiation treatment. The median interval from completion of radiation therapy to presentation of the vesicovaginal fistula is about 8.7 months.

Trauma to the bladder can occur by:
- Inadvertent cystotomy during sharp dissection or a laceration during blunt dissection
- Thermal necrosis during electrocauterization especially during laparoscopic surgery
- Suture placement through both the bladder and the vaginal wall during closure of the vaginal cuff or during an attempt to control pelvic bleeding.

Leakage of urine collects in a pelvic urinoma which ultimately drains out through the vaginal cuff.

Ureteral injuries are almost always in the distal ureter and occur usually during procedure for benign as opposed to malignant conditions. The risk of ureteral injury appears to be greatest during laparoscopic hysterectomy, followed by abdominal, and then by vaginal hysterectomy. The risk of iatrogenic ureteral injury during major gynecological surgery is estimated to range from 0.5% to 2.5%.

MANAGEMENT
Successful treatment of genitourinary fistulas is based on three steps:
1. Perform a thorough evaluation of the fistula and the patient’s general condition.
2. Plan an individualized course of treatment with clear indications for conservative treatment versus operative intervention. The timing and the method of surgical repair should confirm to a deliberate policy.

3. Comfort the patient through the morbidity of urinary leak while she awaits a surgical cure.

**Evaluation**

Detailed evaluation of a genitourinary fistula begins with a focused clinical examination. This is followed by imaging studies and finally by cystoscopy.

**Clinical Examination**

Faced with a postoperative urinary leak from the vagina, one should proceed with clinical examination in a logical sequence. The first step is to carry out a good pelvic examination with visualization of the vagina. Methylene blue is instilled into the bladder. A vaginal leak of the same readily confirms a vesicovaginal fistula. Should there be no such leak, it becomes necessary to ascertain whether the leaking fluid is urine (and not peritoneal fluid, lymphorrhea, or inflammatory exudates), and also whether the leak is from a ureterovaginal fistula. This involves intravenous injection of indigo carmine or methylene blue or the oral administration of phenazopyridine (Pyridium). A stained vaginal swab confirms both suspicions. The three vaginal swab test is useful to indicate the presence of a ureterovaginal fistula, but it does not influence the need for imaging studies which in any case are necessary.

An essential part of the clinical examination is to assess the state of the local tissues (slough, foreign body, inflammatory process, infection and residual tumor). Accessibility of the fistula from the vaginal route should also be taken note of.

**Imaging Studies**

Every genitourinary fistula needs radiological imaging. Three functions need to be served:
1. To ascertain that there is no ureteric involvement either during the initial injury or due to subsequent fibrosis.
2. To examine the surrounding tissue planes for abscess formation or unresolved urinoma.
3. To search for residual malignancy in postradiation fistulas.

A spiral CT scan with 3-D reconstruction is now the standard of care. Its scores over a conventional urogram and cystograms because it can reveal in addition to renal and ureteric anatomy, fluid collections, abscesses, and residual tumor. It also offers detailed perspectives of fistula site in any desired plane. Intravenous urograms, cystograms and even only ultrasonography may be valid options where facilities are restricted.

**Cystoscopy**

Cystoscopy is indispensable. A diligent examination should document the following:

- The number and size of the vesicovaginal fistulas, with their exact location in relation to the ureters and the bladder neck
- The state of the margins of the fistula (slough, suture material, infective debris, residual tumor). If needed a biopsy can be taken from the margin of a postradiation fistula.
- If ureteric involvement has been shown on imaging studies, a retrograde ureterogram and double J stenting can be attempted. For this reason, imaging studies should precede cystoscopy.

**PLAN FOR TREATMENT**

**Conservative Treatment**

Conservative or nonoperative treatment has obvious appeal, but succeeds only occasionally (7–12.5%).

- In a recently developed vesicovaginal fistula, urinary drainage by indwelling catheter, anticholinergics, and antibiotics may be tried for up to 3 weeks. If the fistula does not heal, then catheter should be removed. Persisting with an indwelling catheter for prolonged periods prevents resolution of local infection, prevents regressing of inflammatory edema and ultimately compromises surgical repair.

- Established vesicovaginal fistulas with epithelialized tracks of a diameter less than 3 mm, may be cured by ablating the epithelial lining and draining the bladder for 2–3 weeks. The epithelium may be curetted by an ordinary metal screw or electrocauterized. Fibrin sealant can then be injected into the track. Closure occurs by fibrosis.

- Ureterovaginal fistulas often heal if a double J stent can be maneuvered across the injured ureteral segment and left indwelling for 8 weeks. An aggressive attempt should be made to pass a double J stent across the defect, employing ureteroscopy if called for.

**Surgical Treatment**

Once it becomes clear that conservative measures will not succeed, surgical repair has to be planned. Two issues need clear decisions:
1. When to repair?
2. How to repair?

**Timing of Repair**

A distinctly different approach is used to schedule surgical repair for vesicovaginal fistulas as compared to ureterovaginal fistulas.

**Surgical Repair**

**Vesicovaginal fistulas**: There is an emotionally driven need to seek early relief from the embarassing predicament that the patient and her physician have landed into. A number
Successful fistula surgery is based on these tenets:

- Adequate preoperative correction of anemia, nutritional state, and infection. Local urinomas and abscesses should have been fully resolved.
- Appropriate surgical approach, vagina, abdominal, or laparoscopic.
- Adherence to certain surgical principles during handling of tissues.

**Surgical Approach (Figs 1 to 4)**

Repairs of vesicovaginal fistulas through the vagina is successful, less traumatic (no cystotomy and no repeat laparotomy), less expensive (shorter hospital stay) and significantly easier on the patient (less postoperative discomfort). In only special circumstances should the abdominal route be employed in preference to the vaginal route.

Clear indications for abdominal repair are as these:
- Recurrent fistula and postradiation fistulas which necessarily require the interposition of omentum
- Vesicovaginal fistula repair where a ureter needs to be reimplanted
- Complex uroenteric fistulas
- Severe scarring makes vaginal access difficult
- Shrunken bladders which require augmentation cystoplasty.

Laparoscopic surgery now offers the advantages of abdominal repair at a much reduced morbidity. Procedures like omental interposition and ureteral reimplantation are well within the ambit of laparoscopic repair.

**Tissue Handling Techniques**

- Wide separation of the plane between bladder and vagina to allow multilayered tension-free closure of the defect and also to allow interposition of a viable tissue buttress (omentum or Martius flap).
- Avoid excision of the fistula track as this will enlarge the tissue defect and may even compromise local vascularity when cautery is used for hemostasis. In addition in chronic fistulas, a strong fibrous ring forms outside the epithelialized track that maintains some strength through the repair if this layer is incorporated into the closure.
- Use of adjuvant flaps and grafts to allow the interposition of healthy tissue during vesicovaginal fistula repair.
- Uninterrupted and secure postoperative urinary drainage, using a suprapubic catheter as well as a urethral catheter when required.

**PREVENTION OF GENITOURINARY FISTULAS**

- Ensure an empty bladder during all gynecological operations by constant catheter drainage.
Figs 1A to F: Repair of a high vesicovaginal fistula: vaginal approach
- Perform sharp dissection along anatomical tissue planes; dissect and develop extraperitoneal spaces
- Clamp, cut, suture under direct vision while avoiding large tissue pedicles
- Avoid frantic “blind” attempts to clamp and ligate bleeding vessels. Sustained application of pressure will almost always control the bleeding to allow accurate identification and control of the bleeding vessel
- Avoid excessive use of monopolar electrocautery during laparoscopic surgery

- When planning to operate difficult cases, take care of the following:
  - Position, prepare and drape the patient so as to allow both abdominal and vaginal access
  - Identify the course of each ureter and safeguard it from injury. Preoperative placement of ureteral catheters is neither practical nor desirable as the catheters themselves can cause injury to the ureteral mucosa or impart stiffness to a ureter that may predispose it to devascularization or laceration.\(^8\)
Figs 3A to E: O’Conor’s abdominal repair of vesicovaginal fistula

The bladder is repaired in two layers with absorbable sutures. The first layer skirts the mucosa and approximates the full thickness of the bladder muscle.

The second layer (Lembert like) picks up the seromuscular layer to bury the first suture line.
- Intraoperative testing of the integrity of the urinary tract should be readily resorted to, so that primary repair may be immediately undertaken. This can easily be done by instillation of methylene blue into the bladder or into the ureter. Intraoperative cystoscopy and even cystotomy should be practiced with hesitation.

CONCLUSION

Genitourinary fistulas are an old bête noire that have caused disquieting moments to many a gynecologist. Despite the great advances that this specialty has made, genitourinary fistulas obstinately occur with relentless regularity (about 1 out of 1,800 gynecological procedures).

A slew of new initiatives are establishing themselves.

- Spiral CT scan with 3D reconstruction is emerging as the imaging modality of choice
- The traditional 3–6 month wait with diapers is being discarded in favor of earlier repair
- Laparoscopy is upstaging the stalwart open abdominal repair.

INTRODUCTION

Hysterectomy is one of the most common and major operations in women, and it is therefore vital to make evidence-based decision to choose the appropriate technique of hysterectomy. For years the abdominal route remained the unquestioned traditional route for a hysterectomy with the vaginal route being used in less than a fourth of the population, in the presence of uterovaginal prolapse, and in the absence of the possible need for oophorectomy. This persisted through the years in spite of evidence that was forthcoming in favor of the vaginal route.\(^1\)

The debate on whether the uterus should be removed vaginally or abdominally was sparked when Langenbeck first performed a vaginal hysterectomy (VH) in 1813.\(^2\) Historically, the reason gynecological surgery became a specialty in its own right was its extensive use of the vaginal route. The vaginal approach has always been the hallmark of the gynecological surgeon.

Although VH is the procedure associated with the quickest operating time, the shortest hospital stay, and the lowest hospital costs,\(^3\) many surgeons do not feel comfortable with this approach. Table 1 argues in favor of the vaginal route from the study; still only 20–30% of hysterectomies are carried out vaginally in the western world.\(^4\)

Magos et al.\(^5\) reviewed 500 women who had undergone a hysterectomy by both techniques; 76% were by the abdominal route in the absence of an absolute contraindication (CI) to VH. Among the women operated by the abdominal route, the following characteristics were found; lack of uterine prolapse (76%), fibroid uterus (45%) and need for oophorectomy (43%). It was concluded that with adequate surgical training, more than two-thirds of the patients could have had a VH.

The indications for hysterectomy and the associated conditions are given in Table 2. The fact remains that most cases can be done vaginally if the operator chooses to train himself in the minutiae of the technique. In Brown’s series (cited Sheth SS, 2005)\(^6\) from Australia, 79% of the hysterectomies were completed vaginally. Qureleu and Kovac (cited Sheth SS, 2004)\(^7\) reported 77% and 89% hysterectomies respectively performed by the vaginal route and in the first authors personal series of 7,334 hysterectomies in India,

* Generally, a contraindication to vaginal hysterectomy (VH), it is performed only after counseling as trial VH with laparoscopically-assisted vaginal hysterectomy (LAVH) or laparotomy facility available.

6,044 (82%) were carried out vaginally of which 92% were in the absence of uterovaginal prolapsed.\(^6\)

The preferred method of removing the uterus is almost always determined by the surgeon’s training, preference and experience in a particular technique. However, a gynecologist is now frequently recognized for his/her level of expertise in a particular type of hysterectomy—the one using a laparoscope is looked upon as the most updated and laparoscopic hysterectomy (LH) is being looked upon as the pinnacle of surgical skills, which in reality is far from true. It is unfortunate that abdominal hysterectomy (AH)—the least preferred technique of hysterectomy—is being performed in all categories of patients where vaginal or laparoscopically-assisted vaginal hysterectomy (LAVH) can be performed.

There is little doubt that VH is a more difficult technique to teach and learn than AH, because some steps require careful observation to achieve familiarity with the tissue planes, whereas LH, which is technically more difficult, is aided by the excellent visualization afforded by the modern laparoscopes and television monitors. For VH, the crux of the issue lies in friendliness with the anterior and posterior pouches, i.e. getting access to peritoneum.

The complication rate for AH is 70% higher than that for VH. Western Australia study of 83,000 hysterectomies shared that the occurrence of a serious complication were 20% lower for vaginal hysterectomies compared with abdominal procedures.\(^8\)

In the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) study of 3,798 hysterectomies from the UK, the overall operative complication rate for VH was 3.07% while 3.57% of AH patients were reported to have a complication of surgery and 6.07% of women treated by LAVH experienced a complication.\(^9\) Overall complication rate was 5.3% for VH and 12.6% for AH as concluded from study of 1,427 hysterectomies between 1988 and 1993.\(^10\)

One conclusion of the VALUE study is that laparoscopic techniques tend to be associated with higher complication rates than other methods. Major concern is toward urinary tract injuries. Cystotomy and ureteric injury rate is 1.38% and 0.91% respectively.\(^11\) This rate is far too high when compared with conventional VH. In a review of 1,372 articles in the world literature between 1970 and 1996, the incidence of bladder injury was highest with LH. Postoperative fever which often matters to patient as well as relatives was significantly higher in the abdominal group (18%) compared with 9% and 8% respectively in the vaginal and LAVH groups.\(^6\) Wound infection, which is unlikely after VH, adds 3.5 days to the hospital stay after AH.\(^7\) The chances of leaving behind a sponge are remote with VH. The Collaborative Review of Sterilization Study (CREST) report shows an overall rate for the complication of bleeding of 2.6% with VH and of 1.6% with AH. The CREST study shows that complication of bleeding is more by 1% with VH than with AH.\(^6\) Blood loss is more when VH is associated with repair than without. However, blood transfusion rate is higher with AH than with VH. Operative morbidity, cosmesis and recuperation favor the vaginal approach. It has advantages in recovery, cost, hospital stay, absence of scar and is the least invasive and minimal accessed hysterectomy.

**Stay**

Hospital stay for VH and LAVH is similar, and both are significantly shorter than for AH.\(^12\) Abdominal hysterectomy
will have hospital stay longer by 24–72 hours and this can matter to patient, relatives, hospital and insurance company. In an interesting study, Summitt et al.\textsuperscript{13} showed that, following simple VH, the total hospital stay could average 9.4 hours with 100% patient satisfaction. This study clearly announced that hospital stay can be considerably reduced, to less than 48 hours.

**Cost**

All studies comparing laparoscopic and VH reported laparoscopic hysterectomy to be more expensive\textsuperscript{6} and VH is the least expensive.\textsuperscript{14} Kovac\textsuperscript{10} has contended that if size, access and adnexa are evaluated, 90% of hysterectomies for benign indications could be safely done vaginally, thus saving more than $200 billion each year in the United States—easily more than $1,000 per hysterectomy.

The advent of LH has increased the incidence of recourse to the vaginal route, since the vaginal part of the procedure, (if the correct indications have been followed) is actually much more difficult than performing a VH with a prolapse or with good access. Sutton\textsuperscript{15} emphasizes that what is achieved laparoscopically does not make the vaginal part of the surgery easy. One study has been published assessing the impact of introducing LAVH into a community based gynecological practice, where the rate of VH prior to the advent of LAVH in 1991 was 27.7% and later the incidence had doubled to 53%.\textsuperscript{3} The number of cases of AH has been reduced by 29% with a concomitant increase in the number of VH.\textsuperscript{16} The incidence of AH precipitously fell to 12% from 66% with concurrent rise of LAVH from 0% to 40%\textsuperscript{3} or rise in laparoscopically-assisted Doderlein hysterectomy. This blatantly reflects the down of LH and the generally preferred direction of the route for hysterectomy.

**Randomized Controlled Trials**

Evidence-based medicine shows that the first randomized controlled trial (RCT) was reported by Richardson\textsuperscript{17} from the Royal Free Hospital in London. They had 45 patients in their study and the operating time was much longer with the LAVH, and other measures of recovery and morbidity were similar in the two groups. The other slightly larger study is reported by Summitt et al.\textsuperscript{13} In this study, 56 patients were included who had adequate uterine mobility and a good shaped pelvis. As expected, the operating time in the LAVH group was longer than in the conventional VH group, but other measures suggested little difference between the two approaches, apart from the fact that operative blood loss after conventional VH was significantly greater. This resulted in overall reduction of AH and a corresponding rise in LAVH with automated rise in VH, bringing forth the importance of VH as a technique of first choice.

A randomized study of total abdominal hysterectomy (TAH), VH and LAVH by Ottosen et al.\textsuperscript{18} showed that mean stay in hospital and mean time to recovery was significantly longer for TAH compared with VH and LAVH. It was possible to remove uteri under 600 gm with all three methods.

There are 20 RCTs comparing TAH and VH with LH and 16 RCTs comparing LH with TAH. Almost all trials indicate that LH takes more surgical time with lesser stay and shorter recovery period. Conclusion from 27 trials with 3,643 was, where VH is not possible LH is preferable to AH, although it brings a higher chance of bladder or ureter injury.\textsuperscript{19} Another four studies, though not randomized, clearly suggest that VH should be preferred for hysterectomy, unless specific indications in favor of the abdominal or laparoscopic route are present. Recent papers by Clayton and the Cochrane database reviewed evidence-based hysterectomy studies and Reich concluded that VH is preferable to AH. There is no evidence to support the use of LH if VH can be done safely.\textsuperscript{18–21}

**Quality of Life and Satisfaction**

A prospective study from the technology assessment group at Kaiser Permanente, which examined quality-of-life (QOL) measures, found that patients who had VH returned to normal activity much sooner and had more favorable pain, activity, and function outcomes than patients who underwent either LAVH or AH.\textsuperscript{22} LH had lower mean increase in quality adjusted life years (QALYs) than VH.

Thus, when all clinical decisions are equal, VH appears to provide the most satisfactory outcomes from the patient’s point of view, although QOL outcomes for the laparoscopic procedure were often as favorable and both were superior to AH. Before concluding, results require proof—evidence that convinces and this has accrued out of RCTs and various studies.

### INDICATIONS OR ASSOCIATED CONDITIONS

- For following, benign indications, in absence of contraindication, vaginal route should be a primary route for hysterectomy and performing alternative is certainly not in the best interest of our patient. They are:
  - Dysfunctional uterine bleeding
  - Adenomyosis
  - Fibroid
  - Uterine prolapse
  - Polypsis
  - Carcinoma in situ (CIN III) of cervix
  - High-risk with early endometrial cancer.

- Following associated conditions should never deter gynecologist in selecting vaginal route as primary route for hysterectomy:
  - Nulliparity
  - History of cesarean section
  - Oophorectomy
Indications for Abdominal Hysterectomy

- Uterine size greater than 20–24 weeks size of gestation (VH contraindicated and LAVH risky or very difficult)
- Associated dense adhesions due to endometriosis or pelvic inflammatory disease (PID) or following cesarean in past
- Suspicion of malignancy, e.g. in a rapidly growing tumor
- Adnexal pathology
- Adnexal pathology suspicious of malignancy
- Broad ligament fibroid.
- Associated extragenital surgery or incisional hernia repair from a scar compatible for hysterectomy.

Evidence recommend that AH is indicated when the clinical as well as under anesthesia findings indicate that VH is unsuitable and should not be done, i.e. contraindicated, and LAVH is risky or very difficult.

Contraindications

These are few to take away the option of choosing vaginal route as primary route for hysterectomy. They are:

Common

- Uterus more than 12 weeks’ size or uterine volume more than 250–300 cm³
- Restriction of uterine mobility
- Adnexal pathology.

Uncommon

- Cervix flush with the vagina or past Fothergill’s operation makes the cervix look most unlike a cervix.
- Invasive cancer of the cervix.
- Vesicovaginal and/or rectovaginal fistula repair.
